Table 5 lists some low-power consumption sensor applications that can be integrated with a WPH module. The majority of these sensors were powered by battery with limited lifetime. Once WPH technology is implemented with these applications, it could be used in as a wireless sensor node. In particular, the work presented in [81] utilized RF power harvesting into WSNs for building's structure monitoring. In this work, far-field RF powered wireless sensors were developed with novel data transmission approach to detect humidity, temperature and light inside a building. Results show at a distance of 1 m from 3 W source, the sensor node received 3.14 mW power through air, 1.53 mW of power through 2 inches of brick, 2.88 mW through wood and 0.7 mW through 2 inches of steel. This amount of power is sufficient for the sensors presented in [88, 89, 90, 91]. This result indicates the applicability of RF WPH toward WSNs.

Table 5

State-of-the-art published sensors for WSNs

Ref.	**Sensors**	**Total power consumption (mW)**	**Supplied voltage (V)**	**Power source**	**Applications**
[87]	Pressure	12.69		Battery	Tire pressure monitoring
[88]	Pressure	0.03		Battery	Blood pulses monitoring, small vibration recording
[89]	Temperature	0.0068	1.5-2		RFID, implantable devices
[90]	Temperature	0.065	2.5–5.5		Room temperature monitoring
[91]	Temperature	0.000071	1.2	Battery	Environment monitoring
[92]	Gas	24		DC power source	C_2H_5OH detection
[93]	Gas	2	5		Smart phone gas sensor, air monitor

Furthermore, placement of power transmitters and sensor nodes in WSNs also play a critical role in the efficiency of the system [94, 95, 96]. To enhance directivity of RF transmissions, Shao et al. [97] proposed a beam-steered antenna array to direct its main beam toward energy harvesting units. By controlling the length of transmission line to each antenna unit in an array, the phase radiating difference between units created shift in the main beam. By this way, the harvesting unit remains fed with energy even it was misaligned with the source by 35°. Using the harvesting unit presented in [98] as a demonstration, within 1 min, this system was able to harvest 68.7 μJ at 0° and 13.6 μJ at 35° at a distance of 2 m from the beam-steered source antenna array.

Conclusion

This paper summarized the state-of-the-art of RF power harvesting technology in recent years. This technology will play a key role in replacing batteries in the near future. Some applications of RF power harvesting have been practically realized. A basic RF power-harvesting unit includes three main modules: the antenna, IMN, and voltage multiplier. The total efficiency of the system is dictated by the harmony in the integration of all the modules. The designs and principles of each module were also discussed in the paper.

The RF electromagnetic waves are harmless, abundant in space, and is able to penetrate through soft tissues. Those are properties that make RF electromagnetic waves an alternative source of energy to replace batteries in many applications. Particularly, RF power harvesting supports low-power medical and healthcare devices and facilitates the development of WSNs and IoT by providing mobility of use. Additionally, the progress in integrating RF power harvesting circuits into CMOS technology creates a completely wireless SoC.

Besides progressive accomplishment in recent years, there are still a variety of rooms to further optimize the RF power harvesting technology such as increasing operation range, reducing transmission loss, optimizing PCE, and minimizing system dimensions are the targets of RF power harvesting research. Furthermore, research focusing on harsh working environments for RF WPH such as implantation conditions or underwater zones is attracting much attention to extend the capabilities of this technology. A fine manufacturing and packing process with cost-effective production is necessary to make this technology mature.

In short, the RF WPH technology is gradually becoming a reality. Although this technology still faces many issues, overcoming these challenges can lead the power industry into a new era of clean and sustainable energy.

Declarations

Authors' contributions

LGT carried out literature search and wrote the manuscript. HKC and WTP reviewed/edited the manuscript. All authors read and approved the final manuscript.

(57) **ABSTRACT**

An energy recovery system is provided that can be used in place of a resistive termination. The energy recovery system can simulate the behavior and performance of a resistive termination, while recovering at least some of the energy that would otherwise have been dissipated within the termination. In one embodiment, the energy recovery system includes a rectification system having a plurality of tuned rectifier circuits and an RF input network to provide input power distribution to the plurality of tuned rectifier circuits and input impedance shaping to shape the collective input impedance of the plurality of tuned rectifier circuits as seen at the RF input port of the RF input network.

RF ENERGY RECOVERY SYSTEM

CROSS REFERENCE TO RELATED APPLICATIONS

This application claims the benefit of U.S. Provisional Application No. 61/663,930 filed Jun. 25, 2012 under 35 U.S.C. §119(e) which application is hereby incorporated herein by reference in its entirety.

FIELD

Subject matter disclosed herein relates generally to radio frequency (RF) systems and, more particularly, to techniques for enhancing the power efficiency of RF systems.

BACKGROUND

Many radio-frequency circuits incorporate power resistors that dissipate energy during circuit operation. Such circuits include radio-frequency (RF) hybrids, power combiners and dividers, isolators, duplexers, outphasing RF power amplifiers, composite RF amplifier systems, termination networks and filters, among other devices. In such applications, resistors are often specified as isolation resistors, terminating resistors, dump resistors, etc. While the power dissipation associated with these resistors is undesirable, their terminal characteristics (and absorption of RF electrical power) are typically necessary for proper circuit function. For example, a terminating resistor of a specified resistance value is necessary in an isolating power combiner (such as, for example, a Wilkinson combiner) in order to preserve isolation between the combiner input ports. Likewise, a circulator having a terminating resistor coupled to a port thereof may be used as an RF isolator that passes signals flowing in one direction while terminating signals flowing in an opposite direction. The energy absorption of the resistor coupled to the circulator is required for the isolator to function as intended.

Because efficiency and energy draw are important in many RF applications, the loss associated with such resistors is undesirable. Moreover, the heat generated by such resistors is undesirable and can limit miniaturization of these items and place burdens on supporting devices (e.g., increasing cooling requirements, requiring fans, etc.). It would thus be desirable to realize the electrical function of these power resistors (e.g., providing a nearly constant equivalent resistive input impedance at a specified operating frequency and absorbing RF electrical power), while reducing the dissipation of the absorbed power.

SUMMARY

Systems and techniques are described herein for providing desired operational characteristics of a resistive termination in an RF system, while also allowing power that would normally be dissipated in a resistive termination to be recovered and converted to a useable form.

In accordance with one aspect of the concepts, systems, circuits, and techniques described herein, an energy recovery system is provided that is capable of simulating the behavior of a resistive termination by providing an approximately constant, resistive input impedance to a radio frequency (RF) circuit coupled to the energy recovery system, while recovering energy that would otherwise have been dissipated had a resistive termination been used. The energy recovery system may comprise: a rectification system having a plurality of tuned rectifier circuits and a plurality of rectifier input ports corresponding to the plurality of tuned rectifier circuits, the rectification system to rectify RF energy received at the plurality of rectifier input ports to generate a direct current (dc) signal at one or more rectifier output ports, wherein the tuned rectifier circuits are each tuned to provide an approximately resistive input impedance across a finite input power range; an RF input network having an RF input port and multiple RF output ports, the RF input port forming an input of the energy recovery system and the multiple RF output ports being coupled to the plurality of rectifier input ports of the rectification system, the RF input network to provide input power distribution to the plurality of tuned rectifier circuits and input impedance shaping to shape the combined input impedance of the plurality of tuned rectifier circuits as seen at the RF input port of the RF input network; and a dc-dc converter system having an energy recovery input port and a dc output port, the energy recovery input port of the dc-dc converter system coupled to the output port of at least one rectifier to convert rectified power to a useable dc output voltage, wherein the voltage at the energy recovery input port of the do-dc converter system is regulated.

In accordance with a further aspect of the concepts, systems, circuits, and techniques described herein, a machine implemented method for use in capturing energy output by a radio frequency (RF) circuit comprises: receiving an RF signal from the RF circuit; distributing the RF signal among a plurality of tuned rectifier circuits, the plurality of tuned rectifier circuits to each generate a direct current (dc) signal at an output thereof in response to the RF input signal, wherein the plurality of tuned rectifier circuits are each tuned to provide an approximately resistive input impedance across a finite input power range; providing impedance shaping for the approximately resistive input impedances of the plurality of tuned rectifier circuits to provide an approximately constant, resistive input impedance to the RF circuit; and regulating an output voltage of the plurality of tuned rectifier circuits.

BRIEF DESCRIPTION OF THE DRAWINGS

The foregoing features may be more fully understood from the following description of the drawings in which:

FIG. **1** is a block diagram illustrating an exemplary energy recovery system in accordance with an embodiment;

FIGS. **2**A-**2**F are schematic diagrams illustrating energy recovery dc-dc converter systems in accordance with various embodiments;

FIGS. **3**A-**3**F are schematic diagrams illustrating tuned rectifier circuits that use diodes to perform rectification in accordance with various embodiments;

FIGS. **4**A-**4**B are schematic diagrams illustrating tuned rectifier circuits that use transistors to perform rectification in accordance with various embodiments;

FIG. **5** is a schematic diagram illustrating a rectifier circuit having a series tank and a parallel tank coupled to an input thereof in accordance with an embodiment;

FIG. **6**A is a schematic diagram illustrating an example resistance compression network (RCN) that may be used to provide power dividing and impedance shaping at the input of an energy recovery system in accordance with an embodiment;

FIG. **6**B is a schematic diagram illustrating a higher order RCN that may be used to provide power dividing and impedance shaping at the input of an energy recovery system in accordance with an embodiment;

FIG. **6**C is a schematic diagram illustrating an RCN that utilizes transmission-line sections and reactances to provide power dividing and impedance shaping at the input of an energy recovery system in accordance with an embodiment;

FIG. **6**D is a schematic diagram illustrating a network that provides un-equal power sharing and impedance shaping at the RF input of an energy recovery system in accordance with an embodiment;

FIG. **6**E is a schematic diagram illustrating a network that may be used to provide additional power division using an isolating power splitter to divide power among multiple resistance-compressed rectifier systems in accordance with an embodiment;

FIGS. **7**A and **7**B are schematic diagrams illustrating conversion networks that may be used to transfer energy from a floating input voltage port to a common-referenced output port in accordance with embodiments;

FIG. **8**A is a schematic diagram illustrating an energy recovery system using an isolator as part of the energy recovery system input network in accordance with an embodiment;

FIG. **8**B is a schematic diagram illustrating an energy recovery system using a circulator and providing “multilevel” isolation and energy recovery in accordance with an implementation;

FIG. **9**A is a block diagram illustrating an isolator system using energy recovery at a termination port thereof in accordance with an embodiment;

FIG. **9**B is a block diagram illustrating a combiner/splitter using energy recovery in accordance with an embodiment;

FIG. **9**C is a block diagram illustrating a combiner/splitter using energy recovery that utilizes differential to single-ended conversion in the energy recovery system in accordance with an embodiment;

FIGS. **9**D and **9**E are block diagrams illustrating example power amplification systems using energy recovery in accordance with various embodiments;

FIG. **10**A is a schematic diagram illustrating a transmission-line resistance compression network (TLRCN) providing power dividing and impedance shaping and having an input port and two output ports, with the output ports loaded with a pair of resistive loads;

FIG. **10**B is a plot of the normalized input resistance versus the normalized load resistance for a single-level transmission-line resistance compression network, with the normalized load resistance plotted on a log scale;

FIG. **10**C is a plot showing the ratio of maximum input resistance to minimum input resistance plotted versus the ratio of maximum load resistance to minimum load resistance for a single-level transmission-line resistance compression network, assuming balanced compression;

FIG. **10**D is a schematic diagram illustrating a transmission-line resistance compression network (TLRCN) providing power dividing and impedance shaping and having an input port and two output ports, with the output ports loaded with a pair of resistive loads;

FIG. **10**E is a schematic diagram of an exemplary multi-level transmission-line resistance compression network (TL-RCN) providing power dividing and impedance shaping and having an input port and four output ports, with the output ports loaded with resistive loads; and

FIG. **10**F is a schematic diagram of an exemplary resistance-compressed rectifier system incorporating a multi-level transmission-line resistance compression network (TLRCN) and a set of resonant rectifiers.

DETAILED DESCRIPTION

Systems and techniques are described herein for providing desired operational characteristics of a resistive termination in a radio frequency (RF) system, while also allowing power that would normally be dissipated in a resistive termination to be recovered and converted to a useable form. Likewise, a termination to a radio-frequency power receiver (such as an antenna or coil) that maintains desirable operating characteristics (e.g., providing a constant matched resistive termination) as operating conditions change can capture RF power that would normally be reflected or lost. To recover RF power and convert it to direct current (dc) signals, the power must be rectified. However, rectification presents many challenges in practice, especially at microwave frequencies (e.g., frequencies above 300 MHz).

First, while one may desire a constant resistive input impedance (e.g., 50 Ohms) to realize a desired circuit function, rectifiers at microwave frequencies typically present effective input impedances that are difficult to make resistive and which vary with RF power level and dc output voltage. In systems having a high peak-to-average power ratio, the problem is particularly challenging. Second, harmonics in the RF input or associated with the rectifier system itself can affect rectifier behavior, and harmonic voltages or currents generated at the energy recovery system input by rectifier operation can be problematic to overall system operation. Third, devices capable of rectifier operation at microwave frequencies are often small (and hence cannot individually handle needed power levels), and rectifier circuits employing them are constrained to operate at low alternating current (ac) input voltages and at dc output voltages that may not be useful for utilizing recovered energy. Moreover, at microwave frequencies, the parasitics associated with rectifier devices (such as, for example, device capacitance and package inductance) can have substantial influence on circuit operation, and make it difficult to provide the desired RF input characteristics. Lastly, the RF input port where the resistor is being replaced is often floating with respect to system ground, while the recovered energy must often be provided at an output port that is referenced to system ground. In various aspects described herein, techniques and circuits are provided that make energy recovery at microwave frequencies practical and effective.

FIG. **1** is a block diagram illustrating an exemplary energy recovery system **10** in accordance with an embodiment. As illustrated, the energy recovery system **10** includes: an energy recovery dc-dc converter system **12**, a plurality of tuned rectifier circuits **14**, and an RF input network **16** providing functions such as input impedance shaping, filtering, RF power distribution to the plurality of rectifier circuits, and/or level shifting. As will be described in greater detail, in some alternative embodiments, multiple sets of rectifiers and RF input networks may be coupled to the same energy recovery dc-dc converter. In some other embodiments, an individual energy recovery dc-dc converter system may be provided for each rectifier. Other architectures are also possible.

As mentioned above, one challenge to realizing a practical RF energy recovery system is the fact that effective rectifier input impedance (i.e., the complex ratio of the fundamental component of RF voltage to fundamental RF current at the rectifier input port) depends upon the RF input power level and the rectifier output voltage. Moreover, the output voltage that a practical rectifier device or circuit can operate into is often not at a useful level for utilizing recovered energy. The energy recovery dc-dc converter system **12** is provided to address this challenge.

FIG. **2**A is a schematic diagram illustrating an exemplary energy recovery dc dc converter system **20** in accordance with an embodiment. As illustrated, the energy recovery dc-dc converter system **20** includes a single dc-dc converter **22**. In some implementations (e.g. designs operated to include burst-mode operation), input and output capacitances C_{RO} **24** and C_{OUT} **26** may be provided at the input and output of converter **22** to limit voltage ripple under bursting at frequencies below the converter switching frequency. The energy recovery dc-dc converter system **20** of FIG. **2**A may be used in an energy recovery system that uses, for example, a single do-dc converter (e.g., the energy recovery system of FIG. **1**). As illustrated, converter system **20** includes an input port **28** to be coupled to the outputs of the plurality of rectifiers and an output port **30** to be coupled to a load network to which recovered energy is to be delivered. In order to provide desired impedance characteristics at the RF energy recovery system input, the energy recovery dc-dc converter system **20** may be controlled to regulate the voltage at input port **28** while absorbing the power delivered from the rectifiers and delivering the absorbed power to output port **30**. This can be achieved using, for example, a dc-dc converter such as a buck converter, a boost converter, a flyback converter, a buck-boost converter, or other topology, with control designed to regulate the input voltage of the dc-dc converter. Output power from the converter can be provided to a regulated or unregulated output.

The energy recovery system may often be required to operate at high peak-to-average RF power ratios. Consequently, the instantaneous power delivered to the energy recovery dc-dc converter input port **28** may vary over a wide range. Therefore, in some embodiments, converter **22** may be optimized for operation over a wide range of power levels, including the use of burst mode, cycle skipping, gate-width switching, phase shedding, and related techniques to maintain high efficiency over a wide power range.

In one implementation, the dc-dc converter **22** of FIG. **2**A may be rated for the peak RF power to be recovered, thereby enabling continuous operation at peak RF power conditions. In some applications, however, it is known that such peak power conditions only occur for a limited duration. In these applications, the energy recovery converter input capacitor **24** (or other energy storage element) may be made sufficiently large such that the converter only needs to process a fraction of the peak power rating of the recovery system (but at least the average power rating), while still enabling the voltage at the rectifier output (and the energy recovery converter input **28**) to be regulated to within a desired voltage range.

In many applications, it may be desirable to regulate the energy recovery converter input **28** to a nearly fixed voltage independent of rectifier input power, to provide desired operating characteristics (and effective input impedance values) of the rectifiers and, in turn, desired input impedance characteristics of the energy recovery system. In one exemplary embodiment, this is achieved by comparing the energy recovery power converter input voltage to a reference voltage to generate an error signal, and controlling the converter input current, switch current, burst rate, switching frequency, duty ratio or other control variable as a function of the error signal. That is, in this approach, the converter input voltage is regulated to a value at or near the reference voltage by feedback control of the converter. FIG. **2**D is a block diagram illustrating example circuitry for performing this voltage regulation in accordance with an exemplary embodiment.

Alternatively, the energy recovery converter input voltage V_{RO} may be regulated to a voltage that is a function of the current or power delivered to or from the rectifiers. This can be used to extend the operating power range over which the energy recovery system has desirable effective input impedance characteristics (e.g., 50 Ohms, etc.). To understand this, it should be recognized that the effective input resistance of a rectifier is a function of both the power level at which the rectifier is operating and of the rectifier output voltage. For example, as is known in the art, some rectifiers ideally provide an input resistance at the fundamental operating frequency of the form $R_{eff}=k(V_{RO})^2/P$, where R_{eff} is the effective resistance at the rectifier input, V_{RO} is the rectifier dc output voltage, P is the rectifier output power, and k is a constant that depends on the rectifier topology. For an ideal full-bridge diode rectifier topology, for example, $k=8/\pi^2$. For an ideal voltage-doubler rectifier topology, $k=2/\pi^2$ and so on. By adjusting the energy recovery converter input voltage (rectifier output voltage) to be smaller for low power (or rectifier (or rectifier current) levels, the effective resistance provided by the rectifier can be more approximately constant (vary over a smaller range) than if a constant voltage V_{RO} is used. This can be achieved by adjusting the above-mentioned reference voltage as a function of measured, estimated, or expected power, current or another related variable. It should be noted that to achieve this dynamic reference alternative, it is desirable to size the energy recovery converter input capacitance C_{RO} (in conjunction with any rectifier output capacitance) large enough such that the rectifier output voltage ripple at the RF frequency and harmonics is small, but small enough that the rectifier output voltage can adjust on a time scale associated with the power variations to be compensated. FIG. **2**E is a block diagram illustrating example circuitry for performing voltage regulation with a dynamic reference in accordance with an exemplary embodiment.

FIG. **2**B is a schematic diagram illustrating an energy recovery dc-dc converter system **40** in accordance with another embodiment. In this embodiment, the energy recovery converter **42** is provided with a third port **44** from which energy may be drawn and/or delivered. With a third port, the energy recovery converter **42** can be configured to regulate the voltage at both its input port (V_{RO}) **46** and its output port (V_{OUT}) **48**. For example, in one approach, the converter **42** can be configured as a two-input dc-dc converter with a single output. In another approach, the converter **42** can be configured to transfer power in any direction among the ports **44**, **46**, **48**. Power needed to regulate the output port voltage that is not sourced from the input port (and rectifiers) can instead be sourced from the third port **44**. Typically, the third port **44** will provide an average source of power, but in some cases it may be constructed as a large energy buffer only, such that long-term average power is always sourced from the input port and only temporarily stored at the third port **44**. As described above, V_{RO} may be regulated to a fixed voltage or to a variable voltage.

FIG. **2**C is a schematic diagram illustrating another exemplary energy recovery dc-de converter system **50** in accordance with an embodiment. In this embodiment, a first converter **52** supplied from a third port **54** (V_{P3}) regulates the voltage (V_{RO}) at the energy recovery converter system input port **56** (i.e., the rectifier output), while a second converter **58** is supplied from this voltage and regulates voltage (V_{OUT}) at an output port **60**. While the first and second converters **52**, **58** may both be provided as switched-mode converters, in some applications the second converter **58** (regulating V_{OUT}) may be realized as a linear regulator to reduce noise at the output port **60**. In some embodiments, additional converters powered from V_{RO} may be utilized to regulate additional outputs. The additional converters can each be powered directly from V_{RO} or they can be cascaded so that the output of one converter powers the input of another, and so on.

FIG. **2**F is a schematic diagram illustrating an energy recovery dc-dc converter circuit **100** that may be used within an energy recovery system in accordance with an embodiment. The dc-dc converter circuit **100** uses an off the shelf, integrated, high voltage boost converter IC **102** (e.g., Texas Instruments TPS61170) that is coupled to control circuitry for supporting operation in an energy recovery system. The high voltage boost converter IC **102** has a feedback port that was designed for use in controlling the output voltage of the converter. As shown in FIG. **2**F, the energy recovery dc-dc converter circuit **100** includes logic coupled to the feedback port of the boost converter IC **102** that causes the chip to regulate the input voltage of the converter rather than the output voltage. It should be appreciated that the energy recovery dc-dc converter circuit **100** of FIG. **2**F is an example of one possible converter design that may be used within an energy recovery system in an embodiment. Other converter designs may be used in other implementations.

As described previously, one of the functions of the dc-dc converter system **12** of FIG. **1** is to convert the dc output signal of the rectifier(s) to a useable dc output voltage. As used herein, the phrase "useable dc output voltage" and similar terms refer to voltages that are useable to perform some desired function. In various implementations, the dc output voltage of the converter may be used to, for example, power other circuitry or devices, charge a battery, provide power to a power amplifier and/or to control circuitry, or perform some other function. In each case, the dc-dc converter system may be used to generate a dc output voltage that is useable to support the corresponding function.

As described above, one component in the energy recovery system **10** of FIG. **1** is the rectifier circuit that converts RF to dc. As shown in FIG. **1**, in some implementations, a plurality of rectifiers **14** may be used to provide the overall conversion from RF to dc. A plurality of rectifiers may be used for multiple reasons. First, devices capable of efficient rectification at microwave frequencies are often small and, therefore, may not be able to handle the needed power levels individually. Second, it is often easier to take advantage of circuit parasitics (or mitigate parasitics) for smaller rectifier devices than for larger ones. In addition, as will be described in greater detail, use of a plurality of rectifiers permits a rectifier system to be constructed that provides lower effective input impedance variation than is provided by a single rectifier.

In the discussion that follows, the design of individual tuned rectifier circuits will be described. Techniques for integrating multiple rectifier circuits into a rectification system will be described later. It is desired to have a rectifier that provides approximately resistive effective input impedance (i.e., having the fundamental component of RF voltage substantially in phase with fundamental RF current at the rectifier input port) with as little variation in effective impedance (ratio of fundamental voltage to current) as possible across operating conditions. As is known in the art, the effective impedance presented by a rectifier is a function of power and rectifier output voltage. Moreover, with conventional rectifiers (e.g., implemented with diodes), even the small parasitics associated with device capacitance, package capacitance and package inductance can cause substantial deviations from resistive input impedance. To address these challenges, in at least one embodiment, rectifiers incorporating tuned networks are used, where the tuned networks incorporate device and/or package parasitics to achieve the desired operating characteristics. Such tuned or resonant rectifiers can provide nearly resistive input resistance characteristics across a wide power range (e.g., impedance phase magnitude of less than 20 degrees over more than a 5:1 power range, etc.).

FIG. **3**A is a schematic diagram of an exemplary tuned rectifier circuit **110** in accordance with an embodiment. The tuned rectifier circuit **110** is shown using a Schottky diode **112**, but other device types may also be used (e.g., lateral field-effect rectifiers, etc.). Capacitor **114** represents a capacitance (C_R) including one or more of diode capacitance, diode package capacitance, and added circuit capacitance, and forms part of the tuning network. Capacitor **116** represents the rectifier output capacitance (C_{ROUT}). It provides a low impedance to RF, yielding approximately constant voltage at the rectifier output. Inductor **118** represents the rectifier inductance (L_R) which also forms part of the tuned network. The value of the rectifier inductance (L_R) may include diode package inductance.

In one approach, inductor **118** may be tuned near resonance with capacitor **114** (e.g., L_R on the order of $1/(4\pi^2 f^2 C_R)$). For a given value of C_R, the exact value of L_R can be selected using simulation software, such as SPICE. The network is loaded with a specified fixed output voltage V_{RO} and driven with a sinusoidal input current I_{RF} (at the design frequency), with L_R selected such that the fundamental of V_{RF} is nearly in phase with I_{RF} for a range of current amplitudes. One may adjust the value of C_R (by changing discrete capacitance, diode size, etc.) and subsequently retune L_R in order to achieve resistive operation of the rectifier at a desired range of power levels (and to best utilize the rectifier device capabilities). In some cases, to achieve the best resistive input impedance across power, a small reactance may be added (inductive or capacitive, not shown) in series with the positive RF input terminal of the rectifier **110**. This optional reactance, which would typically be much smaller than the reactance of L_R or C_R, can be used to offset any residual reactance from the tuning process.

FIG. **3**B is a schematic diagram illustrating an exemplary tuned rectifier circuit **120** in accordance with an embodiment. In tuned rectifier **120**, C_{ROUT} is again the rectifier output capacitance, which provides a low impedance at the operating frequency. C_R is the resonant capacitance and incorporates the diode capacitance, and L_R is the resonant inductance and may incorporate diode package inductance. In general, there needs to be a dc current path at the rectifier input. In the embodiment of FIG. **3**B, this path is provided by an explicit inductor (i.e., optional choke inductance **122** (L_{DC})) across the input terminals. In other embodiments, elements external to the rectifier **120** may be used to provide the dc current path. Tuning of this rectifier **120** may be carried out in a similar manner to the rectifier of FIG. **3**A. However, instead of driving the rectifier circuit **120** with a sinusoidal current during tuning, the circuit may be driven with a sinusoidal voltage while observing the fundamental of the rectifier input current.

In some implementations, rectifier circuits may be provided that also include tuning for higher-order harmonics. FIG. **3**C is a schematic diagram illustrating such a tuned rectifier circuit **130** in accordance with an embodiment. As illustrated, the rectifier circuit **130** of FIG. **3**C includes a series tank **132** having an inductance L**2** and a capacitance C**2** tuned at the second harmonic to reduce device voltage stress. Rectifier circuits may also be provided that use transmission-line sections to perform some or all of the tuning function. For example, FIG. **3**D is a schematic diagram illustrating a tuned rectifier circuit **140** using transmission line segments in accordance with an embodiment. As illustrated, the rectifier circuit **140** of FIG. **3**D includes a quarter-wavelength line segment **142** to provide reduced voltage stress. In some implementations, the line length of this segment may be adjusted slightly longer or shorter than a quarter wavelength to compensate for rectifier device capacitance and/or inductance. FIG. **3**E is a schematic diagram illustrating a class E/F rectifier **150** having a differential input port **152** in accordance with an embodiment. This rectifier circuit **150** can be driven differentially, or its input can be converted to a single-ended port using a splitter/combiner. It will be appreciated that other types of tuned rectifier circuit may be used, including those with other harmonic tunings, and those incorporating multiple diodes. In general, the tuning of a rectifier may involve selecting the inductances and capacitances such that the ac current (or voltage) at the rectifier input is substantially in-phase with the ac voltage (or current) at the rectifier input for the frequency of interest.

FIG. **3**F is a schematic diagram illustrating a resistance compressed rectifier system **160** having a pair of tuned rectifiers preceded by a resistance compression network having a pair of 50 ohm transmission line segments in accordance with an embodiment. The resistance compression network acts as an RF input network for the tuned rectifiers (although additional RF input network circuitry may be added in some implementations). The resistance compressed rectifier system **160** of FIG. **3**F is operative at 2.14 GHz with a dc output voltage of 7 V and an RF input impedance near 50 Ohms.

While the tuned rectifier circuits of FIGS. **3**A-**3**F are shown with Schottky diodes, it should be appreciated that other diode types or device types may be employed in other implementations to perform the rectification function. In some implementations, for example, transistors may be used to provide rectification (e.g., MOSFETs, JFETs, HEMTs, HBTs, etc.). FIG. **4**A is a schematic diagram illustrating a tuned rectifier circuit **170** that uses a transistor **172** to perform rectification in accordance with an embodiment. As illustrated in FIG. **4**A, to perform rectification, the gate of the transistor **172** may be biased to an appropriate dc potential (e.g., V_B). Alternatively, the gate terminal may be actively driven at RF to provide synchronous rectification (e.g., V_B in FIG. **4**A may include a dc bias plus an RF signal with appropriate phase relative to V_{RF}). FIG. **4**B is a schematic diagram illustrating a tuned rectifier circuit **180** that performs synchronous rectification using transistors **182**, **184** that are “cross-driven” from the RF input signal itself. In general, synchronous rectification involves turning a transistor on and off with timing such that it carries an average dc current, thus providing conversion from an ac input to a dc output. In one approach, each transistor gate may be driven such that the transistor conducts current of substantially one polarity, and is turned off otherwise. That is, the transistor may be driven to conduct in a manner similar to a diode, but having a lower device drop than a diode.

Another component in the energy recovery system of FIG. **1** is the RF input network **16** that addresses challenges associated with capturing RF energy. These challenges include the generation of undesired frequencies by the rectifiers, the need to operate with small individual rectifier devices, rectifier input impedance variations, operation at high peak-to-average power ratios, and energy capture at circuit ports that are not referenced to a common potential. As will be described below in greater detail, each of these challenges may be addressed by specific elements of the RF input network.

A byproduct of the rectification process is often the presence of dc, switching harmonics, and other undesired frequency components at the rectifier inputs. These undesired frequency components can cause deleterious effects in the energy recovery system. For example, the unwanted frequency content can pollute the system that the energy recovery system is connected to, can cause undesired interactions among the multiple rectifier circuits, as well as other negative effects. To suppress this content, filtering may be provided at the rectifier inputs and possibly at points closer to the energy recovery system input. In some embodiments, these filters may include tuned series and/or parallel tanks in series with the rectifier inputs (and/or interconnections) or in parallel with the rectifier inputs. For example, FIG. **5** is a schematic diagram illustrating a rectifier circuit **190** having a series tank **192** and a parallel tank **194** coupled to an input thereof, where the series tank **192** is tuned to the input frequency to pass through the desired fundamental and the parallel tank **194** is tuned to the input frequency to suppress unwanted content. Other bandpass and/or bandstop filtering (e.g., tuned to harmonics) may also be employed, as well as low-pass and high-pass filters to suppress undesired content. These filters may be implemented with discrete or integrated passive components, with transmission-line sections, or as a combination of these elements.

As described previously, better rectifier performance can sometimes be achieved at RF frequencies using rectifier devices that are small in power rating and physical size, making it advantageous to construct an energy recovery system from multiple rectifiers of reduced power rating. Moreover, utilizing a plurality of rectifiers, one can construct a rectifier system providing lower effective input impedance variation than is provided by a single rectifier, as described in detail below. To implement a multi-rectifier system, in at least one embodiment, the RF input network may include a power dividing and impedance shaping network that splits power among the various rectifiers and provides an input impedance that varies over a smaller range (e.g., a ratio of input resistances or input impedance magnitudes) than the individual rectifiers. Desirable attributes of such a power dividing network include relatively even power splitting among the individual rectifiers and lossless or very low loss operation.

In some embodiments, a resistance compression network (RCN) may be used to provide the power dividing and impedance shaping network of the RF input network. FIG. **6**A is a schematic diagram illustrating an exemplary resistance compression network **200** that may be used in an embodiment. This network is ideally lossless and splits input power among two rectifiers **202**, **204** approximately equally, while providing a resistance at its input port **206** that varies over a smaller range than the individual rectifiers **202**, **204**. This thus forms a “resistance-compressed rectifier system.” The compression branch impedance magnitude X is selected based on the input impedance range provided by the rectifiers **202**, **204**. In constructing RCNs of the type in FIG. **6**A for operation at microwave frequencies, care should be taken to minimize or compensate (e.g., “resonate out”) shunt parasitics at the intermediate nodes (e.g., between the inductors and capacitors).

The resistance compression network **200** of FIG. **6**A, constructed with discrete components, has the benefits of being compact and providing good operational bandwidth. Higher-order resistance compression networks (or “multilevel” compression networks) can also be used, such as the “second order” (or two-level) RCN **210** of FIG. **6**B that can split power among four rectifier circuits **212**, **214**, **216**, **218**. An RCN of order M, or an M-level RCN, can split power among N=2M rectifier circuits. Other RCN variants may alternatively be used, including RCNs that are achieved by topological duality or star-delta transformations of the network elements, RCNs that use different component types to realize the needed reactances, and RCNs that use circuit board or microstrip elements.

Power dividing and resistance compression can also be achieved with circuits incorporating transmission-line sections (e.g., section of microstrip, etc.). FIG. **60** is a schematic diagram illustrating a resistance compression network **230** that uses quarter wavelength transmission line sections **236**, **238** and reactances **240**, **242** to perform resistance compression for first and second rectifiers **232**, **234**. In resistance compression network **230**, the reactive components **240**, **242** may be realized as discrete components, components implemented in the circuit board, or as transmission-line stubs. In this embodiment, in addition to working with the shunt elements to realize resistance compression, the characteristic impedance of the quarter-wave lines **236**, **238** can be selected to provide a desired degree of impedance transformation, FIG. **3**F described previously illustrates the details of an example implementation of a resistance-compressed rectifier system **160** that uses the resistance compression network architecture illustrated in FIG. **60**.

The power dividing and impedance shaping network of the RF input network may also be implemented using other network types and topologies. For example, FIG. **6**D is a schematic diagram illustrating a network **250** that serves to provide a degree of impedance shaping such that the impedance at the RF input **252** varies over a smaller range (e.g., ratio of input resistances or input impedance magnitudes) than the individual rectifiers **254**, **256**, though it does not cause power to be shared equally among the rectifiers **254**, **256** across operating conditions. The network **250** can be extended for use with additional rectifiers by paralleling additional rectifier-loaded quarter-wave-line branches having different characteristic impedances and appropriately designed rectifiers.

Additional power dividing can be obtained using networks that are not ideally lossless and/or which do not provide reduction in impedance range. For example, power may be split further using an isolating power splitter to divide up power to multiple resistance-compressed rectifier systems. FIG. **6**E illustrates a network **260** that uses a two way splitter **262** (e.g., a Wilkinson splitter, a Gysel splitter, a hybrid splitter, etc.) to split power between first and second resistance-compressed rectifier systems **264**, **266**. Many-way splitters can be used when there are more than two resistance-compressed rectifier systems. While providing power dividing in this fashion does not provide additional reduction in impedance ranges, it can be made highly efficient, and the isolation helps soften the variations in input impedance. Moreover, it enables systems of different energy recovery power capacities to be simply constructed.

In some embodiments, the RF input port of an energy recovery system is referenced to a common potential (e.g., ground, etc.). However, in some cases, the input port may be "differential" or floating (or "flying") with respect to system ground, while the recovered energy must be provided at an output port that is referenced to system ground. For example, the isolation port of a Wilkinson combiner is not ground referenced, but represents a "differential" input. One technique to recover energy at a floating or "flying" input port involves the use of an RF transformer or balun to transfer energy from the flying input voltage to a common-referenced port. FIG. **7**A is a schematic diagram illustrating an example conversion network **270** for doing this in accordance with an embodiment. If such an approach is used, the energy may be recovered at the common-referenced port as described above. In the embodiment of FIG. **7**A, energy at port AB **272** is delivered to output port CG **274** with $V_{CG}=(N_2/N_1)\cdot V_{BA}$. If the effective turns ratio is not unity, network **270** also provides an impedance transformation such that $Z_{diff}=(N_1/N_2)^2\cdot Z_{RF}$. Depending on dc levels, one or both of the ports **272**, **274** may require a series blocking capacitor, and one may also need to tune out transformer parasitics (such as leakage inductances and/or magnetizing inductance) at the RF frequency of interest (e.g., using capacitors).

Another technique to transfer energy from a "flying" input port to a common-referenced port for energy recovery purposes involves the use of transmission-line sections. FIG. **7**B is a schematic diagram illustrating an example conversion network **280** that uses transmission line sections **286**, **288**, **290** to transfer energy between ports in accordance with an embodiment. At the design frequency, conversion network **280** transfers energy from a floating port **282** to a common-referenced port **284** according to the relationship $V_{CG}=(Z_1/Z_0)\cdot V_{BA}$. Network **280** can provide both a differential to single-ended conversion and an impedance transformation, such that $Z_{diff}=(Z_0/Z_1)^2\cdot Z_{RF}$. In some cases, the Z_1 transmission line section can be omitted. For example, in cases where the load provided by the energy recovery system is at or near impedance Z_1, the transmission section can be omitted. Similarly, in cases where the impedance inversion provided by the quarter-wave section **290** is not a problem, this transmission line section can be omitted. Also, it will be recognized that blocking capacitors may be used in series with one or more of the terminals of the differential conversion network in some implementations. Note that the network can also be implemented with lumped transmission-line approximations, with other immittance converting circuits taking the function of each quarter-wave section, or combinations of lumped and distributed structures serving the same or similar functions.

Other alternative techniques for converting "flying" or differential inputs to common-referenced outputs for energy recovery can be utilized in other embodiments. Combined with the other portions of the energy recovery system, these techniques enable RF energy to be recovered from "flying" ports.

It is recognized that even with filtering, some applications may be sensitive to any reflected power from the energy recovery system (including at the operating frequency, harmonics, or other frequencies). In such cases, an isolator may be used as part of the energy recovery input network to terminate any reflected power generated by the energy recovery system. As shown in FIG. **8**A, an isolator **300** may be placed at the input of an energy recovery block **302** so that reflections from the input are directed to termination **304**. It should be appreciated that other isolator locations are also possible.

FIG. **8**B is a schematic diagram illustrating an energy recovery system **310** that uses an isolator **312** to provide "multilevel" isolation and energy recovery in accordance with an implementation. As shown, a number of energy recovery blocks **314**, **316** are coupled to ports of isolator **312**. Each energy recovery block **314**, **316** incorporates one or more energy recovery rectifiers and possibly other subsystems, as described above. Multilevel isolation provides the opportunity to capture RF power at different power levels and contents, and may be implemented with a 4 or more port circulator and a terminating resistor, or a cascade of 3-port circulators and a terminating resistor.

The availability of an energy recovery system also enables additional functions and features to be realized. One such function is power monitoring. For example, an additional circuit can be provided that monitors information about the energy recovery system, such as the input and/or output power of the system. In some implementations, the system output power is monitored using the sensing and/or control signals of the energy recovery dc-dc converter, in some other implementations, the output power may be monitored using additional low-frequency sensors or other structures. In at least one embodiment, the input power may be monitored based on the operating point of the rectifier circuits. Alternatively, the input power may be monitored based on the operation of the energy recovery converter (e.g., estimating input power based on the known characteristics of the system and the converter input or output current, voltage, or power or rectifier input or output voltage, current, or power). Additional monitoring circuitry may also be provided in some embodiments. This may include, for example, circuitry for monitoring system temperature, operating status, and/or other critical operating parameters.

Many RF circuits incorporate power resistors that dissipate energy during circuit operation. Such circuits include RF hybrids, power combiners and dividers, isolators, RF power amplifier systems, duplexers, filters and termination networks, among other devices. Each of these circuit types can benefit by incorporating the energy recovery techniques described herein. Likewise, many RF circuits seek to absorb energy from an antenna, transformer secondary, coil, or other means of receiving RF energy, including in rectenna systems, wireless power transfer systems, inductive power coupling systems, radio-frequency power converter systems including RF dc-dc converters, and microwave power transmission systems. It is desirable to be able to capture RF energy in these systems and convert it to useable form, while minimizing reflected or dissipated RF power. Each of these circuit types can likewise benefit by incorporating the energy recovery techniques described herein.

One type of circuit that can benefit from the described techniques is an isolator. FIG. **9**A is a block diagram illustrating the use of an energy recovery system **322** (e.g., the energy recovery system of FIG. **1**, etc.) as a termination for an isolator **320**. As illustrated, the isolator **320** includes a circulator **324** having three ports, with the energy recovery system **322** coupled to one of the three ports (i.e., instead of a conventional resistive termination). A first port of the circulator serves as the input port of the isolator **320** and a second port serves as the output port. RF power delivered to the isolator input port is transferred to the isolator output port. Any power entering the isolator output port (e.g., power reflected back into the isolator output port from a mismatched load and/or any other power) is transferred to the energy recovery system **322** at the third port of the circulator **324**. In this manner, the energy may be at least partially recovered for other uses instead of being lost to dissipation as would occur with a conventional resistive termination.

Another application that can benefit from energy recovery is power combining and/or splitting. FIG. **9**B is a block diagram illustrating the use of an energy recovery system **330** to provide energy recovery for a combiner/splitter **332** in accordance with an embodiment. The combiner/splitter **332** may include, for example, a rat-race hybrid, a branchline hybrid, a 90 or 180 degree hybrid, or others.

In the illustrated embodiment, the combiner/splitter **332** includes four ports: port 1, port 2, a sum port, and a difference (delta) port. The energy recovery system **330** may be coupled to either the sum port or the difference port. The energy recovery system **330** may provide, for example, a proper termination for the corresponding port (e.g., the difference port in FIG. **9**B) while the other port (e.g., the sum port in FIG. **9**B) is used as a "combined" port. In this manner, combining and/or splitting may be achieved between the combined port and ports 1 and 2, while energy is recovered for isolation at the energy recovery output port.

In some systems, three (or more) way combining/splitting may be used. FIG. **9**C is a block diagram illustrating an implementation that utilizes differential to single-ended conversion in an energy recovery system. The combiner/splitter **348** is implemented as a 3-way Wilkinson combiner/splitter with the ports for isolation (with energy recovery) connected in delta, where each differential input port has an apparent input resistance of approximately $3Z_o$. This system uses three energy recovery rectifier systems **340**, **342**, **344**, each including differential-to-single-ended conversion. The system may also include an RF input network comprising impedance shaping, filtering, distribution, and a plurality of rectifiers, along with a single energy recovery dc-dc converter system **350** to provide recovered energy at the output. In an alternative approach, this system can be reconfigured such that there is a separate energy recovery dc-dc converter for each of the energy recovery systems. This technique may be used for splitting or combining any number of signals.

Another application that can benefit from the energy recovery techniques described herein is power amplification. More specifically, systems where power from multiple power amplifiers is combined to create a single higher power signal. FIG. **9**D is a block diagram illustrating an example power amplification system **400** using energy recovery in accordance with an embodiment. As shown, output power from two power amplifiers **402**, **404** is combined using an isolating combiner **406** with energy recovery (e.g., as illustrated in FIG. **9**B). Depending on the relative magnitude and phase of the outputs of the two power amplifiers **402**, **404**, power will be delivered to one or both of first and second output ports of the combiner **406**. The first output port is illustrated as the sum port and the second output port is illustrated as the difference port in FIG. **9**D. An energy recovery system **408** may be connected to the second output port. This provides the opportunity to load the power amplifiers **402**, **404** in an isolating fashion, and at the same time control power (and signal amplitude and phase) delivered to the output port by adjusting the magnitudes and phases of the outputs of the individual power amplifiers **402**, **404**. Power not delivered to the output port is recovered through the energy recovery system **408** (minus any losses). The magnitudes and phases of the outputs of the individual PAs **402**, **404** may be controlled by, for example, any one or more of: (1) individually adjusting one or more of the pulse widths, timing, drive amplitudes, and phases of the power amplifier input signals (e.g., including amplitude modulation, phase-shift or outphasing modulation, PWM modulation, and on/off modulation), (2) individually adjusting the power supply bias voltages of the power amplifiers (e.g., via discrete or continuous drain modulation), (3) load modulation of the individual power amplifiers (e.g., by implementing each power amplifier as a Doherty amplifier or an outphasing amplifier with lossless combining), and/or other techniques. It should be recognized that such a system can also be realized with a larger number of power amplifiers, such as by using the combining and energy recovery system illustrated in FIG. **9**C. Such a system enables high efficiency linear control of output power by adjusting the relative operation of the individual power amplifiers.

A power amplifier system with multiple power amplifiers can also be implemented as a balanced power amplifier system that realizes improved efficiency under load mismatch (e.g., from a non-ideal load impedance) at its output port. FIG. **9**E is a block diagram illustrating an exemplary system **420** of this type. In system **420**, reflected power from an output port of a balanced amplifier **422** is captured by an energy recovery system **424**. The recovered energy is provided at a dc output port **426** and may be used to supply part of the power to the power amplifiers **428**, **430** of balanced amplifier **422**, for powering computation or control circuitry, powering pre-amplifiers, and/or for other uses. The system **420** of FIG. **9**E includes a first 90-degree hybrid **440** to provide appropriate phases at the two power amplifier inputs, and a second 90-degree hybrid **442** to combine power from the two power amplifiers **428**, **430** for delivery to an RF output port. The energy recovery system **424** is connected to the isolation port of the second hybrid **442**. Reflected power entering the output port (e.g., owing to load mismatch) can be substantially captured by the energy recovery system **424**, thus providing improved operation under load mismatch.

Resistance compression networks (RCNs) absorb energy from a source and deliver it (ideally losslessly) to a plurality of loads (e.g., such a set of rectifiers), providing an input resistance that varies over a narrow range as the resistance of the loads vary together over a wide range. Resistance compression networks can also serve to reduce the phase of the input impedance as compared to the phase of the load impedances (phase compression). Ideally, the RCN splits input power substantially equally among the loads. Conventional resistance compression networks use reactances to accomplish this, and may additionally include transmission-line sections, as illustrated in FIGS. **3**F and **6**C. The reactances themselves may be implemented as transmission-line sections or stubs or otherwise realized in printed-circuit form.

In some embodiments, resistance compression networks may be implemented using transmission-line sections having asymmetric lengths, wherein the transmission-line sections are provided as two-port structures interconnecting among the source and loads. Such Transmission-Line Resistance Compression Network (TLRCN) implementations may provide several benefits. For example, they can (a) have low loss, (b) enable repeatable, low-cost implementation using printed circuit techniques, (c) provide filtering, and (d) with correct length selections, they can provide resistance compression at one or more harmonic frequencies. Moreover, at UHF frequencies and above, the discrete reactances often used in conventional RCN designs represent an increasing challenge. That is, the transmission-line effects associated with their physical size can substantially influence system behavior, and their numerical values can become extremely small, making them difficult to implement accurately and making the system susceptible to parasitic effects. TLRCN implementations, on the other hand, avoid these issues by directly realizing the RCN as a transmission-line structure interconnecting the source and loads.

A description will now be made of the theory and operating characteristics of Transmission-Line Resistance Compression Networks. With a TLRCN network, substantially balanced splitting of power to multiple loads and smaller variation in driving point resistance as compared to load resistance variation may be achieved using only transmission-line sections used as two-port devices to connect among the sources and loads. FIG. **10**A shows a basic TLRCN structure, having a single input port with voltage v_{IN} and two output ports with voltages v_{O1} and v_{O2}, with the output ports loaded with identical resistive loads R_L. In each transmission-line section, or branch, in FIG. **10**A the second terminal at each port of each transmission-line section may be treated as connected to a common potential at that end of the transmission-line section, as naturally occurs in a microstrip or other printed-circuit implementation, and is thus not shown explicitly. The first transmission-line branch **500** coupled to the input port has characteristic impedance Z_0 and a length l_1 corresponding to an electrical angular delay θ_1 at an operating frequency of interest. The second transmission-line branch **502** coupled to the input port likewise has characteristic impedance Z_0 and a different length l_2 corresponding to an electrical angular delay θ_2. (Implementation of systems in which the two branches have different characteristic impedances and which operate best with different loading impedances is also possible.) We can express the lengths of the two branches as a base length plus and minus a delta length (or a base angle+/−a delta angle) as follows:

$$l_1 = l_{Base} + \Delta l$$

$$l_2 = l_{Base} - \Delta l \tag{1}$$

$$\theta_1 = \theta_{Base} + \Delta\theta$$

$$\theta_2 = \theta_{Base} - \Delta\theta \tag{2}$$

We obtain desired operating characteristics at a frequency of interest by proper selection of Z_0, θ_{Base}, and $\Delta\theta$.

While there are multiple possibilities for base lengths, we first consider a base length l_{Base} of $\lambda/4$ (a quarter wavelength at a frequency of interest), corresponding to $\theta_{Base} = \pi/2$ radians. (Any base length with an additional multiple of $\lambda/2$ in length will provide similar results.) Considering the first and second branches **500**, **502** in FIG. **10**A individually, we find branch input admittances at the frequency of interest:

$$\begin{aligned} Y_{in,1} &= \frac{1}{Z_{in,1}} = \frac{1}{Z_0} \cdot \frac{Z_0 - jR_L\cot(\Delta\theta)}{R_L - jZ_0\cot(\Delta\theta)} \\ Y_{in,2} &= \frac{1}{Z_{in,1}} = \frac{1}{Z_0} \cdot \frac{Z_0 + jR_L\cot(\Delta\theta)}{R_L + jZ_0\cot(\Delta\theta)} \end{aligned} \tag{3}$$

Since these admittances are complex conjugates, the network will divide power entering the input port equally to both loads (for identical load resistances). The impedance seen at the input port at the frequency of interest is resistive in this case, and can be shown to be:

$$Z_{in} = R_{in}\frac{|\cot(\Delta\theta)|}{2[1+\cot^2(\Delta\theta)]} \cdot \left[\left\{\frac{R_L}{|\cot(\Delta\theta)|}\right\} + \frac{Z_0^2}{\left\{\frac{R_L}{|\cot(\Delta\theta)|}\right\}}\right] \tag{4}$$

Such a characteristic clearly realizes resistance compression: the input impedance is resistive and varies only over a small range as the load resistances vary together over a wide range. In fact, this input resistance characteristic bears close relation to the input resistance of a type of resistance compression network that uses reactances in series with the load networks (e.g., see FIG. **6**A). With a design selection of $\Delta\theta = \pi/4$ radians ($\Delta l = \lambda/8$), the circuit provides identical characteristics (with the transmission-line characteristic impedance Z_0 taking the place of reactance X in the expression for the input resistance).

Using the above-described network with a base angle of $\theta_{Base} = \pi/2$, "balanced" compression can be achieved for a range of load resistances having a geometric mean of $R_{L,center}$:

$$R_{L,center} = Z_0 \cdot |\cot(\Delta\theta)| \tag{5}$$

At this load resistance value ($R_{L,center}$), the input resistance takes on a minimum value of $R_{in,min}$, with larger input resistance for other load resistances. The value of $R_{in,min}$ may be calculated as follows:

$$R_{in,min} = Z_0 \cdot \frac{|\cot(\Delta\theta)|}{[1+\cot^2(\Delta\theta)]} \tag{6}$$

FIG. **10**B shows a plot of the input resistance (normalized to $R_{in,min}$) as a function of the load resistance (normalized to $R_{L,center}$), with the normalized load resistance on a log scale.

FIG. **10**C shows the detail of the ratio of the maximum to minimum input resistance plotted as a function of the maximum to minimum load resistance, assuming balanced compression (i.e., with $R_{L,center}$ selected as the geometric mean of $R_{L,max}$ and $R_{L,min}$). For this case, we find:

$$\frac{R_{in,max}}{R_{in,min}} = \frac{1}{2}\left[\sqrt{\frac{R_{L,max}}{R_{L,min}}} + \sqrt{\frac{R_{L,min}}{R_{L,max}}}\right] \tag{7}$$

Which, for large values of $R_{L,max}/R_{L,min}$ approaches:

$$\frac{R_{in,max}}{R_{in,min}} \approx \frac{1}{2}\sqrt{\frac{R_{L,max}}{R_{L,min}}} \tag{8}$$

The high degree of resistance compression provided by this system can be seen in these expressions and in FIG. **10**C, with a 10:1 ratio of load resistance compressed to a 1.74:1 ratio in input resistance and a 100:1 ratio in load resistance compressed to only a 5.05:1 ratio in input resistance. As with conventional resistance compression networks, one can also use the TLRCN to provide phase compression in which for identical non-resistive loads, the input impedance is more nearly resistive than the load impedances themselves.

It should be noted that other base lengths besides $l_{Base}=\lambda/4$ ($\theta_{Base}=\pi/2$ radians) can be used. For example, a base length of $l_{Base}=\lambda/2$ ($\theta_{Base}=\pi$ radians) likewise results in equal power transfer to the two loads and a compressed resistive input impedance. The characteristics associated with this base length will be the same as that in Equations (3)-(6), except with $\cot(\Delta\theta)$ replaced with $-\tan(\Delta\theta)$ in each expression. Likewise, operation will be the same with any additional multiple of $\lambda/2$ added to the base length. Because of this, with appropriate selections of base length at a desired fundamental frequency, the system can be designed to also provide resistance compression at one or more harmonic frequencies (and at subharmonic frequencies), provided that the loads have appropriate frequency characteristics.

There are multiple possible design approaches for TLRCN circuits. Considering a base length $l_{Base}=\lambda/4$ ($\theta_{Base}=\pi/2$ radians), one may a priori select a value of $\Delta\theta=\pi/4$ radians ($\Delta l=\lambda/8$), such that $\theta_1=3\pi/4$ and $\theta_2=\pi/4$. For balanced compression, one may then select Z_0 as $R_{L,center}$ (the geometric mean of the maximum and minimum load resistances $R_{L,max}$ and $R_{L,min}$). In this case, the load resistances loading each transmission-line section vary (geometrically) about the characteristic impedance of the lines, which helps reduce required transmission-line reflection and loss. This design choice provides a compressed input resistance having a range of values determined by the load resistances. In cases where this range of input resistance values is not what is desired for the system, an additional impedance transformation stage may be placed at the input of the TLRCN. One highly effective means to do this is to add an additional quarter-wave line at the input to the compression stage, as illustrated in FIG. **10**D.

The whole transmission-line structure of FIG. **10**D is likewise itself a resistance compression network having both a compression stage and a transformation stage. The quarter wave line is selected to have a characteristic impedance Z_T that provides an impedance transformation between the resistance obtained at the input of the compression stage (e.g., $Z_{in,median}$, the median of the range of the input resistance Z_{in} or a similar value related to Z_{in}) and that desired for the input of the system ($Z_{in,T}$). In this case, to obtain an overall input resistance near a desired value $Z_{in,T,desired}$, we may select:

$$Z_T=\sqrt{Z_{in,T,desired}\cdot Z_{in,median}}. \tag{9}$$

Another design approach takes advantage of the freedom to choose both the differential length and the characteristic impedance of the transmission lines. One can also choose the base length. In the example that follows, a base length of $\theta_{Base}=\pi/2$ radians at the operating frequency will be used. By properly selecting the differential length and the characteristic impedance, within certain bounds, one can directly realize both resistance compression and a desired specified input resistance directly with the structure of FIG. **10**A. In this design approach, one may start with a center resistance $R_{L,center}$ about which load resistances are compressed. For balanced compression, $R_{L,center}$ is chosen as the geometric mean of the maximum and minimum load resistances, $R_{L,max}$ and $R_{L,min}$. A desired minimum input resistance $R_{in,min}$ of any value below $R_{L,center}$ may then be chosen. The input resistance will take on values at and above $R_{in,min}$, with the range of R_{in} values depending on the range of the R_L values as per Equation (7). One option is to select $R_{in,min}$ to be the desired resistance $R_{in,desired}$ seen at the input of the TLRCN (recognizing that the actual input resistance will be at or above the desired value). Another option is to set the median value of the input resistance that occurs over the range of load resistances to match the desired input resistance. To achieve this for a given maximum to minimum load resistance ratio, one may select $R_{in,min}$ as follows:

$$R_{in,min} = \frac{2\cdot R_{in,desired}}{1+\frac{1}{2}\sqrt{\frac{R_{L,max}}{R_{L,min}}}+\frac{1}{2}\sqrt{\frac{R_{L,min}}{R_{L,max}}}} \tag{10}$$

One could likewise select $R_{in,min}$ to be some other value close to $R_{in,desired}$ to achieve good results.

Based on selecting $R_{L,center}$ and $R_{in,min}$ as described above (with resistance $R_{in,min}$ necessarily selected below $R_{L,center}$), one can directly choose Z_0 and $\Delta\theta$ of the network of FIG. **10**A to provide both the needed compression and impedance transformation, as follows:

$$\cot(\Delta\theta) = \sqrt{\frac{R_{L,center}}{R_{in,min}} - 1} \tag{11}$$

$$Z_0 = \frac{R_{L,center}}{\sqrt{\frac{R_{L,center}}{R_{in,min}} - 1}} \tag{10}$$

This design choice has the advantage of providing both resistance compression and impedance transformation (where needed) in a compact structure. However, the practicality of such an implementation will depend on the desired values. For example, as $R_{in,min}$ approaches $R_{L,center}$, the characteristic impedance of the transmission line can grow unreasonably large. It should also be appreciated that one can use the selection of the transmission-line impedance and differential length to provide a first-degree of impedance transformation, and add another quarter-wave transformer at the input (and/or a set of quarter-wave transformers between the base compression stage and the loads) to provide additional impedance transformation.

As with conventional resistance compression networks, one may construct multi-stage or multi-level compression networks to provide greater degrees of resistance compression than obtained with a single-level design. As with conventional resistance compression networks, this may be done by cascading single-level resistance compression stages in a tree structure, though other structural implementations of multi-level TLRCNs are possible. FIG. **10**E shows an exemplary two-stage TLRCN. This example utilizes $l_{Base}=\lambda/4$ ($\theta_{Base}=\pi/2$ radians), and differential lengths $\Delta l=\lambda/8$ ($\Delta\theta=\pi/4$) radians ($\Delta l=\lambda/8$), such that $\theta_1=3\pi/4$ and $\theta_2=\pi/4$ in each stage. With this selection of differential lengths, a multi-stage TLRCN can be optimized (in terms of minimizing the peak deviation from a median input resistance) just as with conventional reactance-based multi-level RCNs (see, e.g., "A New Power Combining and Outphasing Modulation System for High-Efficiency Power Amplification," by Perreault et al., *IEEE Transactions on Circuits and Systems—I*, Vol. 58, No. 8, pp. 1713-1726, August 2011; and U.S. Patent Publication No. 2011/0187437 to Perreault et al., entitled "Radio-Frequency (RF) Amplifier Circuits and Related Techniques," which is hereby incorporated by reference in its entirety), with the transmission-line characteristic impedances of the lines in the two stages taking the place of the reactance amplitudes of the two stages. Alternatively, both the characteristic impedances and the base and differential lengths of each stage can be optimized to provide an overall desired input resistance level and transformation, with the opportunity to achieve additional goals through the parameter selection, such as minimizing RCN loss.

Combining a transmission-line resistance compression network with a set of rectifiers forms a resistance compressed rectifier system. An exemplary resistance-compressed rectifier system **520** incorporating a TLRCN is shown in FIG. **10**F. This system is for 2.14 GHz operation, and has four tuned rectifiers as loads for the TLRCN that act as approximately resistive loads, each providing ac input impedance of –24-160 t over an input power range of 0.125-1.07 W (and a dc rectifier output power of 0.08-0.85 W) at a rectifier output voltage of 7 V. The rectifier also includes a series-resonant input filter, and is tuned for resistive operation by appropriate resonance between the device capacitance and output inductance. Note that these filtering and tuning elements can be provided as discrete components or constructed in a printed circuit board (optionally including elements such as transmission-line sections, gap capacitors, etc.). The TLRCN has two compression stages and a transformation stage. The first compression-stage "A" compresses the resistances presented by the rectifiers into a range of 31-46Ω (for the first-stage input impedances $Z_{in,A1}$ and $Z_{in,A2}$, which act as the load for the second stage of compression). The second stage further compresses this to an input impedance $Z_{in,B}$ of approximately 9-19.4Ω resistive over the rectifier load resistance range. The transformation stage, comprising a quarter-wave line, transforms this impedance into the overall input impedance of approximately 50Ω.

It will be appreciated that the inventive energy recovery system can be employed in numerous other applications in which energy is conventionally delivered to a resistive termination. By replacing the lossy termination with the energy recovery system, the power that would otherwise be lost can be captured and converted to a useful form, while maintaining a desirable loading characteristic at the termination port.

Having described exemplary embodiments of the invention, it will now become apparent to one of ordinary skill in the art that other embodiments incorporating their concepts may also be used. The embodiments contained herein should not be limited to disclosed embodiments but rather should be limited only by the spirit and scope of the appended claims. All publications and references cited herein are expressly incorporated herein by reference in their entirety.

What is claimed is:

1. An energy recovery system to simulate behavior of a resistive termination for a radio frequency (RF) circuit coupled to the energy recovery system, the energy recovery system comprising:

a rectification system having a plurality of tuned rectifier circuits and a plurality of rectifier input ports corresponding to the plurality of tuned rectifier circuits, the rectification system to rectify RF energy received at the plurality of rectifier input ports to generate a direct current (dc) signal at one or more rectifier output ports;

an RF input network having an RF input port and multiple RF output ports, the RF input port forming an input of the energy recovery system and the multiple RF output ports being coupled to the plurality of rectifier input ports of the rectification system, the RF input network to provide input power distribution to the plurality of tuned rectifier circuits and input impedance shaping to shape the combined input impedance of the plurality of tuned rectifier circuits as seen at the RF input port of the RF input network; and

a dc-dc converter system having an energy recovery input port and a dc output port, the energy recovery input port of the dc-dc converter system coupled to the output port of at least one rectifier to convert rectified power to a useable dc output voltage, wherein the voltage at the energy recovery input port of the dc-dc converter system is regulated.

2. The energy recovery system of claim **1**, wherein:

the rectification system includes a single rectifier output port that carries a combined dc signal of the plurality of tuned rectifier circuits, the single rectifier output port being coupled to the energy recovery input port of the dc-dc converter system.

3. The energy recovery system of claim **2**, wherein:

the dc-dc converter system comprises a dc-dc converter that regulates its input voltage.

4. The energy recovery system of claim **3**, wherein:

the dc-dc converter is configured so that the regulated input voltage of the dc-dc converter changes based, at least in part, on an RF input power level of the rectification system.

5. The energy recovery system of claim **2**, further comprising:

at least one additional RF input network and at least one additional rectification system coupled to the energy recovery input port of the dc-dc converter system.

6. The energy recovery system of claim **2**, wherein:

the dc-dc converter system comprises a three-or-more port dc-dc converter that includes a first port whose voltage is regulated by the dc-dc converter and which receives an output signal of the rectification system, a second port to output recovered energy to a load device, and a third port to provide power to the dc-dc converter for use in regulating the output voltage of the second port.

7. The energy recovery system of claim **6**, wherein:

the third port of the dc-dc output converter is coupled to an energy buffer for use in storing energy to regulate the output voltage of the second port.

8. The energy recovery system of claim **2**, wherein:

the dc-dc converter system comprises a first dc-dc converter having an input port and an output port, the first dc-dc converter input port coupled to the single rectifier output port to convert rectified power to a useable dc output voltage at the first dc-dc converter output port; and

a second dc-dc converter having an output port coupled to an input port of the first dc-dc converter to regulate an input voltage thereof.

9. The energy recovery system of claim **8**, wherein:

the first and second dc-dc converters are both switched-mode converters.

10. The energy recovery system of claim **8**, wherein:

one of the first and second dc-dc converters is a linear regulator and the other of the first and second dc-dc converters is a switched-mode converter.

11. The energy recovery system of claim **1**, wherein:

the rectification system includes multiple rectifier output ports that each correspond to a subgroup of the plurality of tuned rectifier circuits; and

the dc-dc converter system comprises multiple dc-dc converters having regulated input voltages coupled to the multiple rectifier output ports to receive dc signals from the multiple rectifier output ports and covert them to one or more useable dc output voltages.

12. The energy recovery system of claim **1**, wherein:

the RF input network includes a resistance compression network (RCN) to compress the resistance of the combined input impedance of the plurality of tuned rectifier circuits as seen at the RF input port of the RF input network.

13. The energy recovery system of claim **12**, wherein:

the resistance compression network has an order of 2 or greater.

14. The energy recovery system of claim **12**, wherein:

the resistance compression network is a lossless or near lossless network.

15. The energy recovery system of claim **14**, wherein:

the resistance compression network includes a pair of complementary reactances each having a terminal connected to a common potential.

16. The energy recovery system of claim **12**, wherein:

the resistance compression network includes one or more transmission line sections.

17. The energy recovery system of claim **1**, wherein:

the plurality of tuned rectifier circuits includes at least one tuned rectifier circuit that is tuned to provide an approximately resistive input impedance.

18. A machine implemented method for use in capturing energy output by a radio frequency (RF) circuit, the method comprising:

receiving an RF signal from the RF circuit;

distributing the RF signal among a plurality of tuned rectifier circuits, the plurality of tuned rectifier circuits to each generate a direct current (dc) signal at an output thereof in response to the RF input signal;

providing impedance shaping in coupling the input of the RF circuit to the input impedances of the plurality of tuned rectifier circuits to provide an approximately constant, resistive input impedance to the RF circuit; and

regulating an output voltage of the plurality of tuned rectifier circuits.

19. The method of claim **18**, further comprising:

applying one or more dc signals output by the plurality of tuned rectifier circuits to one or more dc-dc output converters, at least one of which has a regulated input voltage, to convert the one or more dc signals to one or more useable dc output voltages.

20. The method of claim **18**, wherein:

providing impedance shaping includes providing resistance compression to compress the input impedances of the plurality of tuned rectifier circuits to provide the approximately constant, resistive input impedance to the RF circuit.

21. The method of claim **18**, further comprising:

combining output signals of the plurality of tuned rectifier circuits to generate a combined output signal;

delivering the combined output signal to a dc-dc output converter to convert the combined output signal to a useable dc output voltage; and

regulating an input voltage of the dc-dc output converter.

22. The method of claim **18**, wherein:

distributing the RF signal among a plurality of tuned rectifier circuits includes delivering a portion of the RF signal to a first tuned rectifier circuit that is tuned to provide an approximately resistive input impedance.

METHOD AND SYSTEM FOR ENERGY RECLAMATION AND REUSE

CROSS-REFERENCE TO RELATED APPLICATIONS

The current application is a continuation application of U.S. application Ser. No. 09/670,613 filed Sep. 27, 2000, which issued as U.S. Pat. No. 6,882,128.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates generally to wireless energy harvesting methods and systems. Specifically, the preferred embodiments of the present invention relate to the integration of antennas and electronics for harvesting ubiquitous electromagnetic energy, transforming that energy into useful power, and storing such power for usage.

2. Description of the Related Art

Typically, energy harvesting techniques and systems are focused on renewable energy such as solar energy, wind energy, and wave action energy from moving water. Solar energy is harvested by arrays of solar cells that convert radiant energy to DC power. Such energy is limited in low-light conditions. Cumbersome wind turbines that convert wind energy to electrical power depend on sufficient wind to spin the blades of the turbines to generate power. Wave action energy is harvested by water turbines or other apparatuses that are capable of converting the energy in the moving water into electrical power. This energy conversion is typically performed at complex hydroelectric power plants or by mechanical/electrical conversion apparatuses, such as those shown in U.S. Pat. Nos. 5,842,838 and 6,045,339 to Berg.

Another approach to energy harvesting is wireless power transmission via focused microwave signals. Unlike the above renewable energy technologies which harvest energy from natural sources, electrical energy of the wireless power transmission technology is remotely harvested and converted from focused microwave signals that are transmitted by a constructed source. For example, U.S. Pat. No. 5,043,739 to Logan et al. discloses a high frequency rectenna device for rectifying electromagnetic energy at microwave frequencies and higher and converting the energy into direct-current (DC) power to conduct wireless power transmission. Applications of this disclosure are focused on high-energy microwave radiation and high temperatures. One such application includes sending power to satellites or high altitude devices from the earth by electromagnetic waves. Another application involves collecting solar power from large space-based arrays of solar cells and transmitting the energy via electromagnetic waves to earth. A third application involves the direct conversion of microwaves generated by fusion reactions into a direct current.

BRIEF SUMMARY OF THE INVENTION

Currently, there is a large amount of renewable electromagnetic energy available in the radio frequency (RF) bands. For instance, AM radio, FM radio, TV, very high frequency (VHF), ultra high frequency (UHF), global system for mobile communications (GSM), digital cellular systems (DCS) and especially the personal communication system (PCS) bands are all lucrative energy sources. These untapped sources of energy grow more and more abundant as a result of the rapid growth in the wireless communication business. Hence, there is a desire to seek new methods and means of collecting the ubiquitous electromagnetic energy (ambient RF noise and signals) opportunistically present in the environment and transforming that energy into useful electrical power.

The preferred embodiments of the present invention can collect ubiquitous ambient radio frequency (RF) electromagnetic energy, convert it to a form useful for powering electronic devices, and store it for reuse. Thus, perpetual self contained subsystems or modules can be realized by using the reclaimed RF energy to power active antenna components, low power circuits, modules and other components such as transceivers, amplifiers, filters, etc. Hence, the preferred embodiments of the present invention can be applicable for any antenna or antenna array, for any antenna physical design (e.g., dipole, monopole, parabolic shape or dish, Yagi, etc.) and any frequency band. In some applications, this technology could be used advantageously and conveniently to transfer power remotely, without a physical connection, using a RF energy source intended for that purpose. In other applications, this technology could be used to maintain devices in a standby sleep mode indefinitely without ancillary power source. Then an RF signal could be used as a triggering mechanism to activate the device. Finally, for low power devices, this technology could provide primary power to the device and eliminate or reduce the traditional battery charge cycle.

Accordingly, the preferred embodiments of the present invention provide an integration of classical antenna physical materials and construction concepts with semiconductor and microprocessor technology to create an antenna structure capable of transforming electromagnetic waves into DC power. This antenna method and system collects and processes RF energy for reuse while simultaneously performing its primary function, such as signal reception, for a specific application. Furthermore, by using either a single antenna element or an array of elements configured to receive a broad range of frequencies in the present invention, energy collection and antenna transmit/receive performance can be maximized and optimized at the same time.

The preferred embodiments of the present invention also provide an Energy Reclamation System (ERS) that collects, converts and stores energy for use from selected frequency bands over the entire electromagnetic spectrum. These selected frequency bands are not required to be contiguous and may based on the operational environment, the application, any physical size limitations, and the technology available to cost effectively integrate an ERS into a device or application. An ERS of the present invention is not restricted to a single energy source because technologies like micro electromechanical systems (MEMS) can be used to integrate the collection of other types of energy, such as electromagnetic energy, solar energy, acoustic energy and/or casual motion energy. Thus, energy diversity enhances an ERS' ability to provide power consistent with the demands of modern devices and applications.

The preferred embodiments of the present invention also provide a method and system for harvesting electromagnetic spectrum energy from unintentional power sources. Thus, the electromagnetic energy may be harvested opportunistically from the abundant ambient RF electromagnetic environment created by the emission of countless commercial RF sources typically present today.

The preferred embodiments of the present invention also provide a method and system for harvesting electromagnetic spectrum energy using efficient wideband omnidirectional antennas for maximizing the collection of RF energy. The antennas can be of any design such as monopole, dipole, Yagi, or contrawound.

The preferred embodiments of the present invention also provide an energy collection and conversion technology that may be used to transmit a control signal to select a device's operating mode (e.g., wake up call in the standby sleep mode). Incorporating this technology into some devices allows them to remain in the sleep mode indefinitely. Thus, the devices may use the continuously reclaimed energy to power the monitoring circuitry and initialize equipment activation as required.

The preferred embodiments of the present invention also provide a method and system for transferring low power levels from an intentional power source advantageously and conveniently. This may be done remotely without a physical connection by using a RF energy source with a focused or blanket radiation pattern and an ERS at the target device. This may be used for numerous applications, including autonomous sensor or communication type applications in any environment (e.g., ground, air, underwater) where the device may use the ERS as its power source backup power source. For example, for underwater sensor locations, energy may come from sonar or other types of energy sources that can propagate with tolerable losses through the water and/or from RF energy delivered to a remote antenna extended above the surface of the water. If remaining operational for extended periods of time requires additional power, the device can be wirelessly and remotely supplied with power for storage and future use.

The preferred embodiments of the present invention further provide a conversion of the energy collected or captured by the antenna or transducer into an electrical current. The electrical current is then converted into a form suitable for input to a selected storage device. For instance, a rectifier and a low pass filter can be used to convert the electrical current into direct current (DC). This power can then be fed into a trickle charger for charging a power storage device, such as batteries, in wireless and other electrical devices. The type of electrical filter and power conditioning used depends on the type of battery or power storage device and the particular process of trickle charging used.

The preferred embodiments of the present invention additionally provide a method and system for harvesting electromagnetic energy that is designed to efficiently collect and convert RF energy using application specific integrated circuit (ASIC) technology. Hence, supporting electronics are integrated with the antenna itself and include, for example, amplifiers, mini-transceivers, trickle chargers for charging micro-cell batteries, filters efficient rectifier design and implementation (with different types of diodes), micro electromechanical systems (MEMS) RF transformers, etc. Thus, embedded circuitries are built into the antenna elements and optimized for a frequency range compatible with any given antenna design.

Additional aspects and novel features of the invention will be set forth in part in the description that follows, and in part will become more apparent to those skilled in the art upon examination of the disclosure.

BRIEF DESCRIPTION OF THE DRAWINGS

The preferred embodiments are illustrated by way of example and not limited in the following figures, in which:

FIG. **1** shows data taken from measurements in the RF spectrum between 3 MHz and 1 GHz in downtown San Diego, Calif., USA;

FIG. **2** shows the results of calculations predicting the signal levels in the AM radio band in downtown San Diego, Calif., USA;

FIG. **3** shows the results of calculations predicting the signal levels in the FM radio band in downtown San Diego, Calif., USA;

FIG. **4** shows the energy reclamation system (ERS) concept in accordance to one embodiment of the present invention;

FIGS. **5**A and **5**B show a physical structure of an energy harvesting antenna and an array of such antennas in accordance to an embodiment of the present invention;

FIG. **6** shows a communication antenna having an insulated shield acting as both a safety shield to the user and an energy harvesting antenna array in accordance to an embodiment of the present invention;

FIG. **7** shows a high level schematic diagram of an Energy Harvesting Subsystem (EHS) in accordance to one embodiment of the present invention;

FIG. **8** shows an energy conversion subsystem (ECS) of a perpetual active antenna (PAA) system in accordance to one embodiment of the present invention;

FIG. **9** shows an application specific integrated circuit (ASIC) chip implementation of the ECS circuitry shown in FIG. **8**;

FIG. **10** shows an array of battery micro-cells of an energy storage subsystem in accordance to an embodiment of the present invention;

FIG. **11** shows a high level schematic diagram of the Two or Multiple Array Sense and Active Mode in accordance to an embodiment of the present invention;

FIG. **12** shows a high level schematic diagram of the Common Antenna Sense and Active Mode in accordance to an embodiment of the present invention;

FIG. **13** shows a high level schematic diagram of the Common Antenna for Simultaneous Energy Harvesting, Sense and Active Mode in accordance to an embodiment of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

The preferred embodiments of the present invention represent a new technology area for the reclamation and reuse of Radio Frequency (RF) power present due to either design or opportunity in certain frequency bands. It was found that RF signals and noise are available in useful power levels in many frequency bands—particularly in the AM, FM, and TV bands as well as the global system for mobile communications (GSM), digital cellular systems (DCS) and communication system (PCS) bands. The abundance of energy available for harvesting is clearly apparent from the measurements of the ambient RF spectrum. For example, FIG. **1** shows one such measurement in downtown San Diego Calif. The measurement indicates the relative power levels of RF signals between 3 MHz and 1 GHz that can be harvested at this location. As can be seen from the figure, there are ample RF signals from which to reclaim energy. FIG. **2** shows the results of calculations predicting the signal levels in just the AM radio band in downtown San Diego. It shows that many of the AM signals approach or are greater than 1 mW (0 dBm). This is because many commercial AM radio transmitters radiate thousands of watts of power. FIG. **3** shows the results of calculations predicting the signal levels in just the FM radio band in downtown San Diego.

These calculations further indicate that there are ample opportunities for harvesting energy from the ambient electromagnetic environment.

Countless candidate devices can benefit from this new energy reclamation technology of the present invention. For instance, the technology can be used for wireless devices that are typically powered by exhaustible or rechargeable batteries. The present invention can be used to provide wireless devices located in certain environments a perpetual life in standby mode and extended normal operational life by using stored reclaimed energy as a power source. The Energy Reclamation System or ERS of the present invention can provide sufficient power (e.g., 0.1-1 mW) to perpetually operate low power wireless devices without external recharging. The ERS of the present invention can also able to provide higher power levels to meet higher demands placed on these wireless devices. According to one preferred embodiment of the present invention, the ERS of the present invention includes a common antenna designed for the energy abundant frequency bands with it's output connected to power conditioning or rectification circuitry appropriately designed for that frequency range. The conditioned or rectified power can then be supplied to a charger (e.g., a trickle charger) or distribution subsystem designed to meet the battery's or storage device's charging specification.

There are innumerable potential applications for the energy reclamation technology of the present invention. For instance, the power harvested from radio frequency (RF) signals can be used for recharging installed power sources, providing power directly to the devices, energizing a device to wake up, and providing emergency backup power for the devices. Countless potential users of this technology also exist. For instance, potential users of the ERS technology may be found in the cellular, personal communications services (PCS) and future generations of wireless communications device industry. Typical consumer wireless electronic products that can be enhanced by ERS technology include, but are not limited to, palm computers, personal digital assistants (PDAs), pocket phones, pagers, cameras, autonomous sensors, garage door openers, remote controls and auto security systems. The energy reclamation technology can also be used in emergency location systems such as GPS position finders, airplane and watercraft emergency beacons and fire alarm systems. The energy reclamation technology can also be applied to wireless personal devices such as video conferencing cell phones, Internet phones and Wireless Personal Area Networks (WPAN). The energy reclamation technology is also flexible enough to be adapted for future electrical and/or electronics applications and devices.

According to a preferred embodiment of the ERS of the present invention, the ERS includes three subsystems: an Energy Harvesting Subsystem (EHS), an Energy Conversion Subsystem (ECS), and an Energy Storage Subsystem (ESS). The Energy Harvesting Subsystem or EHS includes various components used to collect ambient electromagnetic energy via an antenna or antenna array and convert it to electrical current. If acoustic, solar, or motion is the energy source, the antenna or antenna array may be replaced by a transducer or transducer array for the respective energy source. The EHS may also include a combination of antennas and mechanical transducers to collect different types of energy at once or alternately. The Energy Conversion Subsystem or ECS includes circuits, components, and modules integrated together to convert and condition the noise like current out of the antenna or transducer into a form of energy suitable for storage. The Energy Storage Subsystem or ESS includes, for example, batteries, capacitors, and other such components that will store the reclaimed energy for future reuse. The ESS can also include appropriate circuitry (e.g. trickle charger) for charging those devices that the ERS supports.

FIG. **4** shows the ERS concept in accordance to the above preferred embodiment of the present invention. As shown, the ERS **100** includes three parts or subsystems: an Energy Harvesting Subsystem (EHS) **130**, a Power or Energy Conversion Subsystem (ECS) **160**, and a Power or Energy Storage Subsystem (ESS) **190**. The Energy Reclamation System provides for the collection and harvesting of ubiquitous ambient energy over a desired frequency range. In a preferred embodiment, the desired range is 500 KHz-2.4 GHz. For frequencies above 2.4 GHz and for intentionally-radiated high power harvesting applications, the ERS can incorporate the rectenna technology, such as that disclosed in U.S. Pat. No. 5,043,739, into the EHS and the ECS for connection to the ESS. The interconnection of the ESS to the rectenna technology is readily apparent to one skilled in the art.

According to another preferred embodiment of the present invention, the main objective of the ERS **100** is focused on the collection of ambient RF energy present in the ambient environment in the range of 5 watts and below and converting that energy into reusable energy to power numerous electronic devices. The converted energy can be full-wave or half-wave rectified and filtered current. The charging schemes depend on how the ECS **160** is used and its reuse requirements. The output of the ECS **160** can be distributed for reuse to several different types of circuitry. In one embodiment, the converted power may be fed to a trickle charger circuitry that charges a standby energy storage device in the ESS **190** that includes a battery, capacitor, etc. while any excess power is distributed to a charging circuitry for the primary power storage component. Another way to distribute the ECS output power is to feed it directly into circuitry appropriate for affecting indefinite operation of the electronic device in a standby or sleep mode.

The three subsystems of the ERS system are now described in further details.

Energy Harvesting Subsystem (EHS)

The EHS for RF energy collection includes a single antenna of any physical design and shape (e.g., dipole, Yagi, Contrawound Toroidal Helical Antenna, etc.) or an array of such antennas to collect RF energy from any frequency or bands of frequencies. Appropriate baluns (i.e., balanced to unbalanced converters) and impedance matching techniques may be integrated to maximize power transfer into the energy conversion circuitry of the ECS.

For the ERS to reclaim the maximum amount of energy, the energy-harvesting antenna is preferably designed to be a wideband, omnidirectional antenna or antenna array that has maximum efficiency at selected bands of frequencies containing the highest energy levels. If the EHS includes an array of antennas, each antenna in the array can be designed to have maximum efficiency at the same or different bands of frequency from one another. The collected RF energy is then converted into usable DC power using high speed switching semiconductor devices or a diode-type or other suitable rectifier. This power may be used to drive, for example, an amplifier/filter module connected to a second antenna system that is optimized for a particular frequency and application. Thus, one antenna acts as an energy harvester while the other antenna acts as a signal transmitter/receiver. Transforming and/or storing the power garnered by the ERS technology over time makes those devices employing such technology more efficient and extends battery life.

According to a preferred embodiment of the present invention, the antenna design and construction preferably begins with defining a wide band of frequencies over which collection will be required. Next, optimal length or element size is preferably calculated to achieve maximum efficiency over that frequency range. As is apparent to one skilled in the art, antenna efficiency depends on a number of factors related to, for example, the physical design and shape of the antenna. Other factors affecting the amount of energy collected include signal strength at the receiving location from the transmitting source, which in turn depends on the paths from the transmitting source to the ERS of the present invention.

Once the optimal length or element size of the antenna is calculated, it is subsequently reduced to a fraction of a wavelength while integrating semiconductor amplification and impedance matching circuits in the construction of the antenna elements. The antenna circuit elements are preferably constructed using microprocessor wafer manufacturing techniques and shaped for integration or encapsulation in the antenna elements. This preferred design approach reduces the physical size of the antenna while retaining the energy collection efficiencies of a larger antenna. Antenna efficiency of 50% or more is preferred, for higher antenna efficiency resulting in higher energy collection.

FIG. **5**A shows the physical structure of an energy-harvesting antenna and FIG. **5**B shows an array of such antennas in accordance to an embodiment of the present invention. The cylindrical physical design shape was selected for easy explanation of the design concept; however, any physical shape (e.g., toroid, etc.) may evolve that still meets the ERS design concepts and goals. As shown, the antenna **200** includes a standard metal outer sleeve **210**. Under the sleeve **210** is a semiconductor material **215** used to create an apparent physical length optimized for reception to accommodate size limitations. Enclosed by the antenna outer sleeve **210** and semiconductor material **215** is electronic circuitry **220**, which is constructed using microprocessor and ASIC semiconductor technology to develop integrated support modules such as trickle charger, amplifier and filter for the ECS, which will be described later. The outer sleeve **210** may also be used as a heat sink for the electronic circuitry **220**.

According to another preferred embodiment of the present invention, the antenna can also be constructed to comply with recent radiation hazard concerns with wireless and cellular telephone technologies and at the same time increases power collection potential. There are a number of ways to direct the RF energy away from the user or shield the user using cupped shields in the antenna system design. Such design could be optimized to provide an insulated shield and enhance energy collection materials in the antenna system construction. FIG. **6** shows an antenna **210** covered by an insulated shield **232**. The antenna **210** performs its primary function for a specific application, such as receiving RF signals for normal wireless communication. The insulated shield **232** can be used as an electromagnetic shield and also as an ERS antenna or antenna array for energy harvesting. As shown in the figure, the RF shielding material is preferably located on the inside surface **234** of the shield **232**. As is known in the art, the shielding material may be of any material suitable for shielding RF radiation generated by the transmitting antenna **210**. Within the shield **232** is an antenna array **236**, with associated integrated modules of the ECS, for energy harvesting. Alternatively, within the shield **232** is a single antenna for energy harvesting. Each antenna in array **236** or the alternative single antenna is depicted in FIG. **5**A.

FIG. **7** shows a high level schematic diagram of an Energy Harvesting Subsystem (EHS) in accordance to one embodiment of the present invention. The EHS includes a wideband omnidirectional antenna or antenna array **255** for energy harvesting, as described earlier. The antenna **255** may be used to harvest energy from ambient RF signals **3** and/or RF power transfer signal **2** from a remotely-located, intentional power source. It may also be used to concurrently receive the desired communication signal **1** along with the energy-harvesting signals **2** and **3**. The combined signals are then separated by filter bank **250** which will be described in greater detail later.

FIG. **7** also shows that other energy harvesting technologies for collecting ambient solar, acoustical, and mechanical energy can be integrated as part of the EHS to supply electrical energy into the ECS. The electrical energy supplied by these other energy harvesting technologies may interface with the rectifier **162** and/or filter circuitries **250**, which is then fed to filter **275** in the ECS. As apparent to one skilled in the art, the ECS interface depends on the input frequency, quality, quantity and type (constant DC or some form of pulsating DC) of energy supplied.

For ambient solar energy, an array of solar cells or a solar energy conversion device **260** known in the art (such as a MEMS solar/heat electric generator) is preferably used to absorb solar energy from the environment and convert it to electrical energy. This energy is then delivered to a rectifier **162** of the ECS. An array of solar cells may be used to produce sufficient power for a variety of applications.

For ambient acoustical energy, a piezoelectric transducer **266** known in the art can be used to absorb ambient or intentional sound from the environment, which in turn causes a crystal to vibrate and through the piezoelectric effect produce an output voltage. The output energy is then delivered to the rectifier **162** of the ECS. An array of transducers may be used to produce sufficient power for a variety of applications.

For mechanical energy, the energy is preferably converted to electric energy through a MEMS Mechanical Transducer (Generator) **270** known in the art. The MEMS Mechanical Transducer **240** takes mechanical energy derived from the natural acceleration of a thing or person while in transport (e.g., person walking) or in use. These devices can wind a spring, force a piston to move or use some other method to store and convert acceleration energy collected into electrical energy. The output energy is then delivered to the rectifier **162** of the ECS. An array of such transducers may be used to produce sufficient power for a variety of applications.

Energy Conversion Subsystem (ECS)

According to a preferred embodiment of the present invention, the ECS for RF energy collection includes a power charger and other circuitry for performing RF to DC power conversion. Because the energy harvesting in the present invention is focused mainly on recovering small amounts of energy over long periods of time, charging energy storage devices (rechargeable batteries, etc.) may be done over a period of time by trickle charge. As is known in the art, trickle charging is a charging scheme in which a power storage component is charged at a fraction of its capacity rate. FIG. **8** shows an ECS **160** for use in conjunction with the EHS to perform RF to DC power conversion, with specifications in accordance to an embodiment of the present invention.

The ECS **160** preferably includes a transformer **161** connected to an energy harvesting antenna **130** for receiving the RF energy. The transformer **161** is also connected to a diode rectifier circuit **162**. The transformer **161** and the rectifier circuit **162** are designed to match impedance with one another to prevent undesired energy loss between these two elements. After rectification, the converted energy is sent through another transformer **163** and onward to a trickle charger **164**. Again, the second transformer **163** and the trickle charger **164** are designed to match impedance with one another to prevent undesired energy loss between these two elements. The trickle charger **164** is then used to deliver power to a battery **165** for storage and use with an electronic device, such as a standby device **166**. The battery is actually a part of the ESS, which will be described later.

If an array of energy harvesting antennas is used to receive the RF energy, the power collected from all channels (i.e., the power density at all antenna inputs) can be combined, rectified and forwarded to the trickle charger **164**. The power available in each channel is comparable; thus, for example, if 100N nW is required for a load, the power collected in N channels at 100 nW each can be combined to generate the required power.

Although not shown in FIG. **8**, the converted and rectified power may be fed through a filter for signal purification prior to sending it to the transformer **163** and onward to the trickle charger **164**. FIG. **7** shows the use of such filter **275**, with like numbers for like elements shown in FIG. **8**. It should be noted that FIG. **7** depicts a broad overview of the ERS concept according to an embodiment of the present invention; therefore, the figure does not show all detailed components of the ECS as shown in FIG. **8**.

FIG. **9** shows an ASIC chip implementation of the ECS circuitry shown in FIG. **8**. The RF input **280** corresponds to the antenna **130** of FIG. **8** for receiving harvested RF energy; the MEMS RF transformer **281** corresponds to the transformer **161** of FIG. **8**; the RF power ASIC **282** corresponds to the rectifier circuit **162** and the trickle charger **164** of FIG. **8** and any other desired circuitry for the ECS, such as filters, impedance matching circuitry, etc.; and the micro-cell battery **285** corresponds to the battery **165** of FIG. **8**. The battery **165** or **285** is a part of the ESS, which is described next.

Energy Storage Subsystem (ESS)

According to a preferred embodiment of the present invention, the ESS includes a rechargeable battery **165**, which can be a complete battery or an array of micro-cells of battery. If battery **165** includes a complete battery, the trickle charger **164** preferably provides a larger potential difference between terminals and more power for charging during a period of time. If battery **165** includes individual battery cells, the trickle charger **164** preferably provides smaller amounts of power to each individual battery cell, with the charging proceeding on a cell by cell basis. FIG. **10** shows an array of battery micro-cells according to an embodiment of the present invention. The ESS charges one or more micro-cells as available energy allows. As the load requires power, the combined energy is drawn from a charged P×Q subset (sub-array) of the N×M set (array) of cells to power the device on standby or active mode. N, M, P and Q are all natural numbers (i.e., 1, 2, 3, . . .), wherein P is a number less than N, and Q is a number less than M. Charging of the remaining cells continues whenever ambient power is available. As the load depletes cells, switches such as switch **276** are used to replace the depleted cells with charged cells. The rotation of depleted cells and charged cells continues as required. As much energy as possible is banked to ensure adequate power is available on demand. Thus, energy is managed on a micro-cell basis.

According to the present invention, there are numerous ways in which the ERS technology can be configured to harvest RF energy. In one embodiment of the present invention, an electronic device, such as a cellular phone, is preferably designed to have two antennas, one for energy harvesting at a desired frequency band and one for performing RF communication at a different frequency band. An example of this dual-antenna design is previously shown in FIG. **6**. FIG. **11** shows a high level schematic diagram **300** of a dual-antenna design ERS in accordance to one embodiment of the present invention. As explained earlier, the frequency band at which an antenna receives and transmits signals depends on the physical dimensions of the antenna. Thus, the energy-harvesting antenna **310** and the communication antenna **320** are designed with different dimensions to receive signals at their respectively desired frequency bands. The energy-harvesting antenna **310** may comprise one antenna or an array of like antennas. In this embodiment, parallel operations are possible for energy harvesting and communication. In other words, a user can be using the phone for wireless communication in one frequency band, while at the same instance the energy harvesting antenna **310** and associated circuitry within the phone is collecting electromagnetic energy in another frequency band. The collected electromagnetic energy is passed to integrated circuitry that converts the RF energy into electrical energy. This electrical energy is then distributed for storage in batteries of the ESS **340** for use in powering various electrical components of the phone.

As shown in FIG. **11**, communication signals received by the device antenna **320** are sent to communication processing circuitry **390** for transmission and reception. The energy harvesting antenna **310**, on the other hand, is connected to an Energy Conversion Subsystem or ECS **330**, which is designed to match the impedance and frequency band or bands of the energy harvesting antenna **310** for maximizing input energy received. The ECS **330** is as described earlier with respect to FIG. **8**. Its output is conditioned power coming from a trickle charger designed to efficiently charge the power storage devices, such as NiCd, NiMH, or LiIon battery cells, in the energy storage subsystem or ESS **340**. Any excess conditioned power from the trickle charger of the ECS **330** is then distributed to the device's main power source **380**.

The ESS **340** is as described earlier with respect to FIGS. **8** and **10**. It stores the standby power and distributes it to the electronic switching circuitry **350** and the Monitor and Activation Circuitry **360** in both active and standby modes of the device. Alternatively, the ESS **340** may be used to power circuitries **350** and **360** in standby mode of the device, while the device power source **380** powers those circuitries in the device's active mode. The ESS **340** may also be used to complement the device power source **380**.

According to yet another embodiment of the present invention, the harvesting antenna **310** and associated circuitries **330** and **340** may be physically located outside of the cellular phone but yet capable of electrical coupling with the phone. For example, the harvesting antenna **310** and associated circuitries may be built into portable physical structures such as briefcases, suitcases, purses, and wearable apparel (cloths) or fixed physical structures by any known means in the art. Thus, when the phone is desired to be charged, it can be stored in any of the aforementioned physical structures and electrically coupled to the built-in harvesting antenna and circuitry for charging purposes. These separate structures facilitate the use of larger antennas (transducers) or arrays of smaller elements whichever is most efficient for collecting the ambient energy. In any case, the larger surface area intercepts more energy.

According to a further embodiment for harvesting RF energy in the present invention, an electronic device, such as a cellular phone, is designed to have two antennas that respectively harvest RF energy and perform wireless communications in the same desired frequency band. In this embodiment, the energy-harvesting antenna and the communication antenna are designed with the same physical dimensions. The communication antenna is connected to a signal level detection system for detecting the strength of RF signals in the desired frequency band. If the strength of the desired RF signals is sufficiently high to sustain both RF communication and energy harvesting, then the level detection system will cause the activation of the energy-harvesting antenna. Thus harvesting proceeds in parallel with communication and the RF energy is converted into electrical power useful for powering various components of the cellular phone without degrading phone service.

According to another embodiment for harvesting RF energy in the present invention, a single antenna or an array of like antennas in an electronic device, such as a cellular phone, is used for both energy harvesting and communication purposes. FIG. **12** shows a high level schematic diagram **400** of the Common Antenna for Simultaneous Energy Harvesting, Sense and Active Mode in accordance with this embodiment. This mode requires modifications to the device's antenna switching and filter circuitry to allow communication signals in along with collected RF energy for harvesting. The communication signals are filtered and directed to the receiver's communication circuitry while the noise or interference portions of the received RF signals are filtered out and sent to the energy harvesting circuitry within the electronic device. This noise filtering technique is illustrated back in FIG. **7**, where incoming communication signals **1** and the ambient RF energy **3** are filtered by a filter bank **250**, which may reside in the switching circuitry **450** shown in FIG. **12**. The communication signals **1** are then directed to the receiver's communication circuitry **255**, which is shown as communication processing circuitry **490** in FIG. **12**, while the noise or interference RF portions **3** are filtered out and sent to the energy harvesting circuitries, which include the ECS **430** and ESS **440**.

According to still another embodiment for harvesting RF energy in the present invention, a single antenna or an array of like antennas in an electronic device, such as a cellular phone, is again used for both energy harvesting and communication purposes. FIG. **13** shows a high level schematic diagram **500** of the Common Antenna Sense and Active Mode in accordance with this embodiment. Here, the single antenna or antenna array **510** is connected to the energy harvesting circuitries **530** and **540** and communication circuitry **590** by a switch **550**, which is slaved to the various powering modes of the electronic device. For example, when the phone is in the power-on mode, the switch **550** is programmed to connect the antenna **510** with the communication circuitry **590** to receive the RF communication signals and enable wireless communication with the phone. However, when the phone is in the standby mode, the switch is programmed to connect the antenna **510** with the harvesting circuitries, which then converts the electromagnetic energy in the same RF communication signals into electrical power for powering the electronic device in the standby mode.

The normal operation of an electronic device having the ERS technology as depicted in FIGS. **11** and **12** may also include a standby or sleep mode, as described above with regard to FIG. **13**. When the electronic device is set in a standby mode, the electronic switching circuitry (**350** or **450**) of the ERS (**300** or **400**) within the electronic device is placed in a Sense Mode. As shown in both FIGS. **11** and **12**, the monitor and activation circuitry (**360** or **460**) is used to set the electronic switching circuitry (**350** or **450**) in a sense mode. In this mode, signals received by the device's communication antenna (**320** or **410**) are sent to a band pass filter (**370** or **470**) to retrieve an activation signal, which is passed on to the monitor and activation circuitry (**360** or **460**) that is watching for the activation signal. The activation signal can be anything defined by the device's manufacturer, such as a trigger signal or an emergency beacon for activating a desired system. When a turn-on signal brings the electronic device out of standby mode, the monitor and activation circuitry (**360** or **460**) sends an active signal to the electronic switching circuitry (**350** or **450**) to connect the communication antenna (**320** or **410**) to the device's communication circuitry (**390** or **490**). The device's turn-on signal may be manually provided by a user turning on the electronic device, or it may be brought on by the reception of the activation signal by the monitor and activation circuitry (**360** or **460**).

Again, the harvesting circuitries in the above embodiments may be physically located apart from the communication circuitry. For example, the harvesting circuitries may be built into portable structures such as briefcases, suitcases, handbags, and purses by any known means in the art, while the communication circuitries and the switch are built into the phone itself. Thus, when the phone is desired to be charged, it can be stored in any of the aforementioned portable structures and electrically coupled to the harvesting circuitries built into the structure for charging purpose.

Although only a few exemplary embodiments of this invention have been described in detail above, those skilled in the art will readily appreciate that many modifications are possible in the exemplary embodiments without materially departing from the novel teachings and advantages of this invention. Accordingly, all such modifications are intended to be included within the scope of this invention as defined in the following claims. Furthermore, any means-plus-function clauses in the claims (invoked only if expressly recited) are intended to cover the structures described herein as performing the recited function and all equivalents thereto, including, but not limited to, structural equivalents, equivalent structures, and other equivalents.

The invention claimed is:

1. An energy reclamation device, comprising:

a radio frequency (RF) energy collector for receiving ambient RF energy;

a solar energy collector for receiving ambient solar energy;

a vibration energy collector for receiving ambient vibration energy;

at least one conversion circuit for converting the ambient RF energy, the ambient solar energy, and the ambient vibration energy to electrical power; and

a power storage for storing the electrical power;

wherein the RF energy collector comprises one antenna to receive RF signals and wherein the received RF signals are sent to the at least one conversion circuit only when the energy reclamation device is in standby mode.

2. The energy reclamation device of claim **1**, wherein the at least one antenna is designed to receive ambient RF energy in a selected frequency range.

3. The energy reclamation device of claim **1**, wherein the RF energy collector comprises a plurality of antennas.

4. The energy reclamation device of claim **3**, wherein an antenna in the plurality of antennas transmits and receives RF signals used for communications.

5. The energy reclamation device of claim **1**, wherein the ambient RF energy comprises ambient RF signals.

6. The energy reclamation device of claim **1**, wherein the solar energy collector comprises an array of solar cells.

7. The energy reclamation device of claim **1**, wherein the vibration energy collector comprises a piezoelectric transducer.

8. The energy reclamation device of claim **1**, wherein the ambient vibration energy comprises ambient acoustic energy.

9. The energy reclamation device of claim **1**, further comprising a mechanical energy collector for receiving ambient mechanical energy and using the at least one conversion circuit to convert the ambient mechanical energy to electrical power.

10. The energy reclamation device of claim **9**, wherein the mechanical energy collector comprises a mechanical transducer.

11. The energy reclamation device of claim **9**, wherein the ambient mechanical energy is derived from acceleration of the energy reclamation device.

12. The energy reclamation device of claim **1**, wherein at least one conversion circuit comprises a rectifier.

13. The energy reclamation device of claim **1**, wherein the at least one conversion circuit is formed on an application specific integrated circuit (ASIC) chip that is integrated with the RF energy collector, solar energy collector, and the vibration energy collector.

14. The energy reclamation device of claim **1**, wherein the power storage comprises a battery.

15. The energy reclamation device of claim **14**, wherein the battery comprises a plurality of battery micro-cells.

16. The energy reclamation device of claim **15**, further comprising a trickle charger for charging the battery micro-cells on a cell by cell basis.

17. The energy reclamation device of claim **1**, wherein the power storage comprises a plurality of batteries.

18. The energy reclamation device of claim **1**, wherein the electrical power is equal to or less than five watts.

19. The energy reclamation device of claim **1**, wherein the RF antenna to receives RF signals comprising ambient RF signals and RF signals used for communications.

20. The energy reclamation device of claim **19**, further comprising a filter for filtering the received RF signals into an interference portion and a communication portion.

21. The energy reclamation device of claim **19**, wherein the interference portion of the received RF signals is sent to the at least one conversion circuit and the communication portion of the received RF signals is not sent to the at least one conversion circuit.

22. An energy reclamation apparatus, comprising:

a base component;

a radio frequency (RF) energy collecting component for receiving ambient RF energy;

a solar energy collecting component for receiving ambient solar energy;

a vibration energy collecting component for receiving ambient vibration energy;

at least one conversion component for converting the ambient RF energy, the ambient solar energy, and the ambient vibration energy to electrical power used to power the energy reclamation apparatus;

a power storage component for providing additional electrical power to the energy reclamation apparatus if the energy reclamation apparatus requires more electrical power than is converted by the at least one conversion component; and

wherein the RF energy collecting component, the solar energy collecting component, vibration energy collecting component, the at least one conversion component, and the power storage component are mounted onto the base component;

wherein the RF energy collecting component comprises one antenna to receive RF signals and wherein the received RF signals are sent to the at least one conversion component only when the energy reclamation device is in standby mode.

23. The energy reclamation apparatus of claim **22**, further comprising a switching component for receiving an activation signal indicating whether the energy reclamation apparatus is in power-on mode or standby mode.

24. The energy reclamation apparatus of claim **23**, further comprising an activation component for receiving the activation signal from the switching component.

25. The energy reclamation apparatus of claim **22**, wherein the at least one antenna is designed to receive ambient RF energy in a selected frequency range.

26. The energy reclamation apparatus of claim **22**, wherein the RF energy collecting component comprises a plurality of antennas.

27. The energy reclamation apparatus of claim **26**, wherein an antenna in the plurality of antennas transmits and receives RF signals.

28. The energy reclamation apparatus of claim **22**, wherein the ambient RF energy comprises ambient RF signals.

29. The energy reclamation apparatus of claim **22**, wherein the solar energy collecting component comprises an array of solar cells.

30. The energy reclamation apparatus of claim **22**, wherein the vibration energy collecting component comprises a piezoelectric transducer.

31. The energy reclamation apparatus of claim **22**, wherein the ambient vibration energy comprises ambient acoustic energy.

32. The energy reclamation apparatus of claim **22**, further comprising a mechanical energy collecting component for receiving ambient mechanical energy and using the at least one conversion component to convert the ambient mechanical energy to electrical power.

33. The energy reclamation apparatus of claim **32**, wherein the mechanical energy collecting component comprises a mechanical transducer.

34. The energy reclamation apparatus of claim **32**, wherein the ambient mechanical energy is derived from acceleration of the energy reclamation apparatus.

35. The energy reclamation apparatus of claim **22**, wherein at least one conversion component comprises a rectifier.

36. The energy reclamation apparatus of claim **22**, wherein the at least one conversion component is formed on an application specific integrated circuit (ASIC) chip that is mounted onto the base component.

37. The energy reclamation apparatus of claim **22**, wherein the power storage component comprises a battery.

38. The energy reclamation apparatus of claim **37**, wherein the battery comprises a plurality of battery micro-cells.

39. The energy reclamation apparatus of claim **38**, further comprising a trickle charging component for charging the battery micro-cells on a cell by cell basis.

40. The energy reclamation apparatus of claim **22**, wherein the power storage component comprises a plurality of batteries.

41. The energy reclamation apparatus of claim **22**, wherein the electrical power generated by the at least one conversion component is equal to or less than five watts.

42. The energy reclamation apparatus of claim **22**, wherein the RF energy collecting component receives RF signals comprising ambient RF signals and RF signals used for communications.

43. The energy reclamation apparatus of claim **42**, further comprising a filter component for filtering the received RF signals into an interference portion and a communication portion.

44. The energy reclamation apparatus of claim **43**, wherein the interference portion of the received RF signals is sent to the at least one conversion component and the communication portion of the received RF signals is not sent to the at least one conversion component.

(57) **ABSTRACT**

The present invention discloses a solar cell comprising a nanostructure array capable of accepting energy and producing electricity. In an embodiment, the solar cell comprises an at least one optical antenna having a geometric morphology capable of accepting energy. In addition, the cell comprises a rectifier having the optical antenna at a first end and engaging a substrate at a second end wherein the rectifier comprises the optical antenna engaged to a rectifying material (such as, a semiconductor). In addition, an embodiment of the solar cell comprises a metal layer wherein the metal layer surrounds a length of the rectifier, wherein the optical antenna accepts energy and converts the energy from AC to DC along the rectifier. Further, the invention provides various methods of efficiently and reliably producing such solar cells.

SOLAR CELLS USING ARRAYS OF OPTICAL RECTENNAS

RELATED APPLICATIONS

[0001] This application claims the benefit of U.S. Provisional Application Ser. No. 60/619,262, filed Oct. 15, 2004, the entirety of which is hereby incorporated herein by reference.

GOVERNMENT SUPPORT

[0002] The present invention was made with partial support from The US Army Natick Soldier Systems Center under Grant Number DAAD16-02-C-0037 and partly by NSF under the grant NIRT 0304506. The United States Government retains certain rights to the invention.

FIELD OF INVENTION

[0003] The embodiments disclosed herein relate to nanoscale energy conversion devices having optical rectennas, and more particularly to high-efficiency solar cells having arrays of optical rectennas capable of receiving and transmitting solar energy and converting the solar energy into direct current electricity.

BACKGROUND OF THE INVENTION

[0004] The concept of using a rectifying antenna (rectenna) to collect solar energy was first proposed by R. L. Bailey in 1972; Since then, different approaches have been taken toward a practical fabrication of solar cells using optical rectennas. To date, however, no substantial progresses in practice have been reported due to major difficulties in achieving large-scale metallic nanostructures at low cost.

[0005] Recently, periodic and random arrays of multi-walled carbon nanotubes (MWCNTs) have been synthesized on various substrates. Each nanotube in the array is a metallic rod of about 10-100 nm in diameter and 200-1000 nm in length. Therefore, one can view interaction of these arrays with the electromagnetic radiation as that of an array of dipole antennas. MWCNTs arrays have been studied in order to determine the antenna-like interactions, since the most efficient antenna interaction occurs when the length of the antennas is of the order of the wavelength of the incoming radiation.

[0006] U.S. Pat. No. 6,038,060, U.S. Pat. No. 6,258,401, and U.S. Pat. No. 6,700,550 disclose various attempts at producing optical antenna arrays. However, there remains a need in the art for high energy conversion devices that employ optical antennas capable of receiving energy and converting AC current into a DC current. In addition, there is a need in the art for an efficient, reproducible method of producing such solar cells.

SUMMARY OF THE INVENTION

[0007] The present invention discloses a solar cell comprising a planar substrate having a top side and a bottom side. The solar cell comprises an at least one optical antenna having a geometric morphology capable of accepting energy. In addition, the cell comprises a rectifier having the optical antenna at a first end and engaging the substrate at a second end wherein the rectifier comprises the optical antenna engaged to a rectifying material. Also, the solar cell comprises a metal layer wherein the metal layer surrounds the rectifier from the top of the substrate to the optical antenna, wherein the optical antenna accepts energy and converts the energy from AC to DC along the rectifier.

[0008] Further, the present invention discloses a solar cell comprising a planar substrate having a conductor layer below a semiconductor layer. In addition, the cell comprises an array of carbon nanotubes engaging the semiconductor layer at a first end and comprising an optical antenna at a second end. In addition, the solar cell comprises a passivation layer wherein the passivation layer surrounds a length of the carbon nanotubes, wherein the optical antenna accepts energy and delivers energy to the solar cell wherein AC is rectified to DC.

[0009] In addition, the present invention discloses methods of producing such solar cells. In an embodiment, a method is disclosed for producing a solar cell which comprises growing a plurality of vertically-aligned nanotubes on a substrate and depositing a layer of a rectifying material onto the nanotubes. In addition, the method comprises depositing a layer of metal to cover a length of the nanotubes.

BRIEF DESCRIPTION OF THE DRAWINGS

[0010] The presently disclosed embodiments will be further explained with reference to the attached drawings, wherein like structures are referred to by like numerals throughout the several views. The drawings are not necessarily to scale, the emphasis having instead been generally placed upon illustrating the principles of the presently disclosed embodiments.

[0011] FIG. **1** is a schematic diagram showing an energy conversion device of the disclosed embodiments having a dipole antenna design.

[0012] FIG. **2** is a schematic diagram showing an energy conversion device of the disclosed embodiments having a bow-tie antenna design.

[0013] FIG. **3** is a schematic diagram showing an energy conversion device of the disclosed embodiments having a loop antenna design.

[0014] FIG. **4** is a schematic diagram showing an energy conversion device of the disclosed embodiments having a spiral antenna design.

[0015] FIG. **5** is a scanning electron microscopy image of an energy conversion device of the disclosed embodiments having a bow-tie antenna design.

[0016] FIG. **6** shows method steps for synthesizing an energy conversion device of the disclosed embodiments having a dipole antenna design.

[0017] FIG. **7** shows method steps for synthesizing an energy conversion device of the disclosed embodiments having a dipole antenna design.

[0018] FIG. **8** shows an example of a solar cell created using a number of energy conversion devices of FIG. **7**.

[0019] FIG. **9** shows the electrical connections to the energy conversion device of FIG. **7**.

[0020] FIG. **10** shows an energy conversion device of the disclosed embodiments having a CNT-semiconductor tunnel junction at a distal end of the CNT.

[0021] FIG. **11** shows an example of a solar cell configuration using a number of energy conversion devices.

[0022] FIG. **12** shows how large-scale assemblies of energy conversion devices can be formed where neighbor cells share a common cable to simplify connections.

[0023] FIG. **13**A shows a scanning electron microscope (SEM) image of an array of aligned MWCNTs. FIG. **13**B shows an SEM image of an array of scratched MWCNTs.

[0024] FIG. **14** shows a graph illustrating polarization effect.

[0025] FIG. **15** shows interference colors from the random array of MWCNTs.

[0026] FIG. **16** shows a graph illustrating reflected light intensity radiation wavelength measured in selected points on the sample shown in FIG. **15**.

[0027] FIG. **17** shows calculated reflected light intensity spectra for a model array of random antennas for various nanotube lengths.

[0028] FIG. **18** shows average length of MWCNTs versus wavelength of the incoming radiation at the corresponding maxima of reflected light intensity.

[0029] While the above-identified drawings set forth presently disclosed embodiments, other embodiments are also contemplated, as noted in the discussion. This disclosure presents illustrative embodiments by way of representation and not limitation. Numerous other modifications and embodiments can be devised by those skilled in the art which fall within the scope and spirit of the principles of the presently disclosed embodiments.

DETAILED DESCRIPTION

[0030] The embodiments disclosed herein relate to the field of energy conversion devices and more particularly to a solar cell using random arrays of nanotube optical rectennas. The following definitions are used to describe the various aspects and characteristics of the presently disclosed embodiments.

[0031] As referred to herein, "carbon nanotube", "nanowire", and "nanorod" are used interchangeably.

[0032] As referred to herein, "nanoscale" refers to distances and features below 1000 nanometers (one nanometer equals one billionth of a meter).

[0033] As referred to herein, "single-walled carbon nanotubes" (SWCNTs) consist of one graphene sheet rolled into a cylinder. "Double-walled carbon nanotubes" (DWCNTs) consist of two graphene sheets in parallel, and those with multiple sheets (typically about 3 to about 30) are "multi-walled carbon nanotubes" (MWCNTs).

[0034] As referred to herein, CNTs are "aligned" wherein the longitudinal axis of individual tubules are oriented in a direction substantially parallel to one another.

[0035] As referred to herein, a "tubule" is an individual CNT.

[0036] The term "linear CNTs" as used herein, refers to CNTs that do not contain branches originating from the surface of individual CNT tubules along their linear axes.

[0037] The term "array" as used herein, refers to a plurality of CNT tubules that are attached to a substrate material proximally to one another.

[0038] As referred to herein, a "catalytic transition metal" can be any transition metal, transition metal alloy or mixture thereof. Examples of a catalytic transition metal include, but are not limited to, nickel (Ni), silver (Ag), gold (Au), platinum (Pt), palladium (Pd), iron (Fe), ruthenium (Ru), osmium (Os), cobalt (Co), rhodium (Rh) and iridium (Ir). In an embodiment, the catalytic transition metal comprises nickel (Ni).

[0039] The terms "nanocrystals,""nanoparticles" and "nanostructures," which are employed interchangeably herein, are known in the art. To the extent that any further explanation may be needed, they primarily refer to material structures having sizes, e.g., characterized by their largest dimension, in a range of a few nanometers (nm) to about a few microns. In applications where highly symmetric structures are generated, the sizes (largest dimensions) can be as large as tens of microns.

[0040] The term "CVD" refers to chemical vapor deposition. In CVD, gaseous mixtures of chemicals are dissociated at high temperature (for example, CO_2 into C and O_2). This is the "CV" part of CVD. Some of the liberated molecules may then be deposited on a nearby substrate (the "D" in CVD), with the rest pumped away. Examples of CVD methods include but not limited to, "plasma enhanced chemical vapor deposition" (PECVD), "hot filament chemical vapor deposition" (HFCVD), and "synchrotron radiation chemical vapor deposition" (SRCVD).

[0041] A nanoscale energy conversion device of the presently disclosed embodiments is shown generally at **100** in FIG. **1**. As a brief overview, FIG. **1** shows an embodiment of an optical rectenna **125**. The optical rectenna **125** engages a substrate **110** at a first end and comprises an optical antenna **120** at a second end. The optical antenna **120** receives energy from an outside source and delivers the energy to the solar cell **100**. Further, FIG. **1** shows a rectifier **115** wherein the rectifier **115** comprises a rectifying material **130** engaged to the antenna. Various embodiments of each of these elements is discussed below.

[0042] Referring to FIG. **1**, a nanoscale energy conversion device (solar cell) **100** includes a metal substrate **110** having an array of optical rectennas **125** penetrating the metal substrate **110** and extending beyond the top surface of the metal substrate **110**. Only a single optical rectenna **125** is visible in FIG. **1**, however, an array of optical rectennas **125** exists. The optical rectenna comprises an antenna engaged to a rectifying material **130**. In an embodiment, the rectifying material **130** is an insulator. In an embodiment, the rectifying material is a semiconductor material **130**. In an embodiment, the rectifying material **130** is air. In an embodiment, the rectifying material **130** is a vacuum. The rectifying material **130** may be engaged to the antenna, either before the antennas are grown on the metal substrate **110** or after they are grown on the metal substrate **110**. A thick layer of metal **140** is deposited onto the optical rectennas **125** and portions of the optical rectennas **125** are exposed. The portions of the optical rectennas **125** that are exposed form optical antennas **120** and the portions of the optical rectennas **125** that are embedded in the thick layer of metal form the rectifier (in the form of transmission lines) **115**. In an embodiment, the portion of the optical rectennas **125** that are exposed to the semiconductor material **130** (tunnel junction) results in a rectifying diode. In an embodiment, the semiconductor material **130** is coated onto the optical rectennas **125** after they are grown, such that the optical antenna-semiconductor junction produces a rectifying diode.

[**0043**] The rectifier **115** is capable of rectifying optical frequency alternating current (AC) into direct current (DC) electricity. The optical antennas **120** are connected to a nanowire electrode embedded in the metal substrate **110**, in a vertical configuration (the rectifier section). The array of optical antennas **120** may form various geometric morphologies. In one embodiment, the geometric morphology of the optical antenna is similar to that of conventional microwave antennas. In one embodiment, the geometric morphology is a dipole antenna design. In one embodiment, the geometric morphology is a bow-tie antenna design (non-linear antenna design). In one embodiment, the geometric morphology is a loop antenna design (such as, an antenna forming a loop, parallel to the ground yielding a non-linear antenna design). In one embodiment, the geometric morphology is a spiral antenna design (non-linear antenna design). These designs are, shown respectively in FIGS. **1**, **2**, **3** and **4**. These various configurations allow for the antennas to have various bandwidth response, various directional response patterns with respect to the direction of wave propagation as well as the polarization, and various impedance matching options. Those skilled in the art will recognize that various geometric configurations are within the spirit and scope of the present invention.

[**0044**] In one embodiment, the optical rectennas **125** may be fabricated from a metal nanorod. In one embodiment, the nanorod comprises aluminum. In one embodiment, the nanorod comprises gold. In one embodiment, the optical rectennas comprise carbon nanotubes. In one embodiment, the optical rectennas comprise a dielectric material. Those skilled in the art will recognize that the optical rectennas may comprise various materials and remain within the spirit and scope of the present invention.

[**0045**] Techniques for fabricating the energy conversion device **100** include, but are not limited to, top-down electron beam lithography and bottom-up nanostructure synthesis. In an embodiment, the array of optical antennas **120** forms a dipole antenna design and fabrication of the optical rectennas **125** may be performed using aligned carbon nanotubes grown by a plasma-enhanced chemical vapor deposition method. In an embodiment, the array of optical antennas **120** forms a bow-tie antenna design and fabrication of the optical rectennas **125** may be performed using microsphere lithography where triangular islands with one edge facing each other can be achieved in large scale (as shown in the scanning electron microscopy image of FIG. **5**).

[**0046**] FIG. **6** illustrates a method of fabricating an energy conversion device **100** having a dipole nanoscale optical antenna design. In step **600**, vertically-aligned optical rectennas **125** may be grown, or lithographically created on a metal substrate **110**, that can be etched or dissolved later. In step **620**, a thin intermediate layer, of an insulator **130** (including, but not limited to, SiO_2) or a semiconductor **130** (including, but not limited to, doped or undoped Si, SiC or GaAs), is deposited onto the recntennas **125**. In step **640**, a thick layer of metal **140** (including, but not limited to, Au or Ag) is deposited (by evaporation or sputtering) to cover the rectennas **125**. In step **660**, the surface of the device may be polished, causing the protruding optical antenna **120** tips to be broken up and removed together with the conductive materials coated on the tips, thus exposing the optical antennas **120** cross sections, as shown in step **660**. The optical antennas **120** are in contact with the semiconductor material **130** resulting in a tunnel junction.

[**0047**] The material of the antenna **120** and rectifier **115** sections can be properly chosen to activate plasma resonances, resulting in an enhancement of the antenna **120** response. Nanostructures of gold and silver have plasmonic frequencies in the visible frequency range that may be tuned by changing the antenna **120** geometry. Thus, the electrical field response may be intensified by a factor of several orders of magnitude, both in the case of the antenna **120**, as well as in the rectifier **115**.

[**0048**] The configuration of the embedded rectennas **125** resembles that of a transmission line, impedance matching of which (to the antenna section) may be easily achieved. The energy collected by the antennas **120** will be concentrated in the transmission lines **115** (embedded in the metal substrate **140**) where it is rectified and converted into electricity. The total area of the rectification area, e.g. the transmission line, may be of any size, not limited by the scale of the incident wavelength. The difference of the instantaneous electric field strength on the opposing antennas **120** and metal surfaces **140** causes electrons to tunnel through the intermediate layer (insulating or semiconducting) **130** having an asymmetric barrier height at the two junctions, resulting in net current flow.

[**0049**] When relatively narrow bandwidth antennas **120** are used, stacks of layers of rectenna structures **125** with different working frequencies may be used to respond collectively to a wide solar spectrum (for example, in a dipole design). Alternatively, the same could be achieved by implementing arrays of antennas **120** with random length. If in addition to random length a random orientation of antennas **120** is used, response to an unpolarized light will be maximized.

[**0050**] In an embodiment, a bottom-up procedure is used to fabricate high-efficiency energy conversion devices using random arrays of aligned multi-walled carbon nanotubes (MWCNTs) as the optical rectennas. The MWCNTs are synthesized on substrates by the plasma-enhanced chemical vapor deposition (PECVD) process. The bottom-up fabrication procedure utilizes MWCNTs both as the optical antennas and in the rectifying diodes. A configuration of MWCNT-semiconductor (CNT-Sc) tunnel junction is able to rectify optical frequency AC currents into DC currents. The CNT-Sc configuration features high reproducibility, low series resistance, and low cost.

[**0051**] The bottom-up fabrication procedure takes advantage of nanomaterial synthesis and novel transparent conductive materials and is carried out by a scalable layer-by-layer technique. The use of conductive and semiconducting transparent materials of the presently disclosed embodiments is compatible with large-scale industrial production.

The high-efficiency energy conversion devices disclosed herein are capable of intrinsic energy conversion efficiencies of over about 80%, featuring amplified output current and minimum internal resistance. The characteristics of MWCNTs make the disclosed energy conversion devices useful in a variety of areas such as optoelectronic devices, such as THz and IR detectors and solar cells.

[0052] Aligned MWCNT arrays grown on silicon substrates using PECVD act as optical rectennas, receiving and transmitting light at ultraviolet (UV), visible and infrared (IR) frequencies. Most of the MWCNTs grown by PECVD methods are shown to be truly metallic. In addition, MWCNT-metal junctions have been found to be ohmic and MWCNT-semiconductor junctions have been found to have rectifying behaviors like schottky diodes. The work function of MWCNTs have been measured and found to be close to the work function of graphite which is highly conductive. Recent in situ tunneling electron microscopy studies have shown that the growth of MWCNTs starts off with several graphite layers parallel to the substrate surface at the CNT-substrate interface.

[0053] As is shown in example 1 below, it has been shown that MWCNTs interact with light in the same manner as simple dipole radio antennas. In particular, MWCNTs show both the polarization and the length antenna effect. The first effect is characterized by a suppression of the reflected signal when the electric field of the incoming radiation is polarized perpendicular to the CNT axis. The second, the antenna length effect, maximizes the response when the antenna length is a proper multiple of the half-wavelength of the radiation. The characteristics make the devices disclosed herein useful in a variety of areas such as optoelectronic devices, such as THz or and IR detectors.

[0054] To functionalize MWCNTs as optical rectennas, a femto-second rectifier must be engaged to each MWCNT to change the optical frequency AC current into DC current. An asymmetric metal-insulator-metal (MIM) tunnel junction structure has been disclosed for fabrication of such ultra-fast diodes. However, the methodology requires an unlimited selection range of materials and a very accurate control of the insulating layers thickness at the atomic scale. This greatly restricts the reproducibility and scalability in the practical process. For the case of MWCNTs as an example, the work function is restricted to about 4.9 eV which is prohibitively big compared to the visible frequency photon energy 1.8-3.2 eV The number of available transparent conductive materials is also very limited. Indium Tin Oxide (ITO) is one of such materials that is the most widely used in industry and has a work function in the range of 4.3eV-5.5 eV. Thus, the CNT-insulator-ITO junction will only work in the low-voltage scenario in both forward and reverse biases where the net current density is extremely small ($<10^{-6}$ Acm^{-2} for barrier thickness of 2 nm).

[0055] The disclosed embodiments provide for a CNT-Sc tunnel junction structure at one end of each individual CNT in order to form a rectifying diode. The CNT-Sc tunnel junction can be at either a distal end of the optical antenna (i.e., near the tip) or at a proximal end of the optical rectenna (i.e., at the end where the rectenna and the substrate are formed). The characteristics of the CNT-Sc tunnel junction resemble a conventional metal-semiconductor tunnel junction due to the intrinsic metallic property of the MWCNTs. The CNTs should have an average diameter of less than about 70 nm for significant quantum mechanical tunneling effect to dominate the thermionic emission. The choices of semiconductors are broad, and include, but are not limited to, heavily doped Si, GaAs, SiGe, Sic, and GaN (-type or n-type, doping density $>10^{19}$ cm^{-3} for barrier thickness ~3 nm). For multi-layer fabrications, transparent semiconductors are employed, including, but not limited to, ZnO:Al (AZO, n-type), $SrCu_2O_2$ (SCO, p-type), and $CuAlO_2$ (CAO, p-type), whose doping levels may be well controlled. Ohmic contacts to heavily doped silicon may be achieved by evaporating (sputtering) a catalytic material such as Al, Au, or Ni, onto the silicon and sintering at about 400° C. Ohmic contact to n-ZnO may be achieved by depositing n^+-ZnO. Ohmic contact to p-SCO may be achieved by depositing In_2O_3:SnO_2 (ITO) onto the semiconductors at low temperature respectively. Sputtering targets of these oxide materials are widely available and suitable for large-scale production. The net forward tunneling current density of CNT-(p)Si heterojunctions has been shown to be on the order of 10^{-3} Acm^{-2}-$10^{-2}Acm^{-2}$ under a bias voltage of 1.8V-3.2V. The CNT-Sc tunnel junctions disclosed herein may result in a higher order of magnitude.

[0056] A method of fabricating an energy conversion device **700** using a bottom-up procedure is shown in FIG. **7**. In step **700**, a semiconducting thin film **710** (such as, p^+-Si) is deposited onto a conductive substrate **705** (such as, Al), and standard procedures are carried out to form an ohmic contact. A catalytic material **715**, such as, Ni, Fe, or Co, is deposited onto the semiconducting film **710** using DC magnetron sputtering. In an embodiment, the catalytic material **715** is Ni. The desired length and diameter of the carbon nanotubes (CNTs) are achieved by accurate control of the growth parameters. The deposition thickness of the catalytic material **715** has a direct affect on the average diameter of the aligned CNTs grown. Without being limited to any particular theory, the difference in the average diameter is most likely due to the fact that Ni films of different thicknesses break into catalytic particles of different average sizes by heat treatment during the growth procedure, step **720**. Table 1 lists data showing the average diameters of aligned CNTs grown in a PECVD system resulting from different deposition thickness of Ni as the catalytic material **715**. Clean aligned CNT **715** arrays with Ni particles on top can then be grown using a DC glow discharge plasma in an atmosphere of NH_3 and C_2H_2, as shown in step **740**. Mixing ratios of about 4:1 or about 2:1 can be used. A growth time of about 1-2 min, yields CNTs **715** around or shorter than 1000 nm. The morphology of the CNTs **715** including length, diameters, straightness, etc., can be finely tuned by the other growth parameters such as plasma intensity and etching time, temperature, and total growth time. By modifying the growth parameters, and/or the geometry of the bias voltage electrodes, a nonuniform growth of CNTs **715**, with average length varying across the sample, can also be achieved. In this configuration, at the bottom of each individual CNT **715**, a nano-scale CNT-Sc tunnel junction is formed which rectifies the AC current excited within each antenna into a DC current at optical frequencies.

TABLE 1

[0057] A highly transparent passivation layer **725** is then spin-coated in between the CNTs, as shown in step **760**, up to a height h of $\lambda/4n-d$ or $\lambda/2n-d$ (50 nm-500 nm for visible and near infrared), where λ is the wavelength of incident light in vacuum and n is the refractive index of the passivation material **725**. In an embodiment, the passivation layer **725** is a PMMA/copolymer layer, a silicone elastomer layer or another polymeric material layer. The spin-coating can be performed by varying the viscosity of the polymer solution and the spin rate. After baking (usually <200° C.), a thin film (thickness $d \ll \lambda/4n$ or $\lambda/2n$) of transparent conductive material **730** (such as Indium Tin Oxide (ITO) or n^+-(Zinc Oxide (ZnO)) is deposited on top of the passivation layer **725** and the exposed part of CNTs **715** by e-beam evaporation or sputtering, as shown in step **760**. The CNTs **715** grow sufficiently long ($>\lambda/4n$ or $\lambda/2n$, respectively) so that, by carefully polishing the surface at this stage, the protruding CNT **715** tips will be broken up and removed together with the conductive materials coated on the tips, exposing the CNT **715** cross sections, as shown in step **780**. The cross sections tend to be automatically closed or partially closed through the collapse of the CNT **715** walls near the open end. The CNT-transparent conductive material contacts are ohmic. An additional thin layer of the same passivation material **725** may be again spin-coated on top to provide a uniform dielectric medium surrounding the CNT antennas and protect the CNT antennas from outside attacks. A configuration where all the CNT rectennas **715** as individual current sources are connected in parallel is so achieved and the rectified DC currents will add up to a much higher magnitude accompanied by a substantially reduced total internal resistance of the rectennas **715**. The two conductive layers can be connected across an external load as DC electrodes, as shown in step **790**. The so-established single-wavelength energy conversion device, upon the incident light of wavelength λ polarized in the direction of CNT **715** alignment, will convert the photon energy into DC electricity at an efficiency greater then about 90%.

[0058] As shown in FIG. **8**, a solar cell **800** that catches the whole solar spectrum is constructed by the following arrangement of single-wavelength energy conversion devices **700** disclosed in FIG. **7**. The semiconducting films **710** and the substrates **705** are made of transparent materials. Devices **700** of different wavelength capabilities are cascaded together one below another. The ordering is such that the shorter the wavelength the upper the device **700** (in z direction), since it is easier for longer wavelength to penetrate through the media. All the devices **700** are then wired up in parallel to yield large current and small internal resistance. The electrical connections to each device **700** can be prepared during the original layer-by-layer construction process of the device **700** (see FIG. **9**). The solar cell **800** disclosed herein is capable of collecting full solar spectrum of photons polarized in the CNT direction at an efficiency greater than about 85%.

[0059] As shown in FIG. **10**, the order of the conductive film and the semiconducting film **710** can be interchanged by growing optical rectennas **715** from a conductive substrate **705** and depositing a semiconducting film **710** on the rectennas **715** later. Since the tip, side and bottom of CNTs have different atomic structures, there may be practical merits in this flexibility of changing the junction location. Another advantage of the top CNT-Sc junction configuration is that even smaller contact area can be achieved, if the thickness of the semiconducting film **710** is smaller than a quarter of the CNT diameter. It also means that the CNT diameter can be relatively large, which is easier for growth control and maintenance of CNT straightness during process, while still having a small enough contact area to reduce the parasitic capacitance and increase the switching frequency of the CNT-Sc junction by making the semiconducting film **710** sufficiently thin.

[0060] FIG. **11** shows an embodiment of a solar cell **1000**, where full spectrum unpolarized sunlight may be efficiently converted to DC electricity. The solar cell **1000** is composed of multi-levels (for simplicity, two levels A and B are shown) with shorter wavelength energy conversion devices **1050** closer to the exposed surface and longer ones farther away. Within a single level, there are three sublevels (I, II and III), each consisting of a stack of identical single-wavelength energy conversion devices **1050**. The solid arrows denote the CNT growth directions in the stacks. The three stacks (I, II and III) are so oriented that the CNT array in each aligns with a different orthogonal 3-dimensional axis. The two sublevels of CNTs parallel with the exposed surface (in x-y plane) may be made as wide as possible ($l \gg 10$ μm) but have to be sufficiently thin ($t<10$ μm, ~100 CNT layers) by using devices of strip-shaped substrates for good transmission. Fabrication of substrate strips at this scale may be achieved using contemporary photolithography. The other sublevel in which CNTs are oriented perpendicular to the exposed surface (in z direction) has no limitations in dimensions but the number of devices in a stack, which are larger dimension devices, is compensated so that every sublevel contains similar number of CNTs. The three sublevel configurations (I, II and III) are repeated from one level to another. Although in levels of longer CNTs, an increment in the thickness of the two parallel sublevels seems necessary for maintaining an equivalent CNT quantity to that in shorter CNT levels, the fact that the solar radiation has lower power in longer wavelengths actually predicts a lower demand for the quantity of longer CNTs, thus ensuring no significant change in level thickness along the z direction. If the average bandwidth of each level is about 50 nm (high selectivity) for half-wave antennas according to surface plasmon measurements, the total solar cell thickness should be on the order of about 1 mm. Currently, the best transparent polymeric material has a transmittance of over 95% at this scale of thickness. The solar cell device **1000** is supported on the bottom by a reflecting mirror **1100** facing up for secondary absorption.

[0061] According to the electrical connection pattern shown in FIG. **11**, all the energy conversion devices **1050** are connected in parallel and the currents merge into two major cables located besides the diagonal ridges of the solar cell

1000, resulting in a useful setup when producing large dimension single solar cells is practically prohibitive. The setup allows multiple solar cells to be further integrated into large-scale assemblies where neighbor cells share a common cable to simplify connections (FIG. **12**, top view). All the cables terminate on the surface, ready to be finally collected by a set of parallel wires. The energy conversion efficiency of the solar cell device **1000** is greater then about 80%.

[**0062**] The following provides an example of an embodiment of the current invention. The example in no way is meant to limit any aspect of the current invention.

EXAMPLES

Example 1

[**0063**] With this example, optical measurements of random arrays of aligned carbon nanotubes are disclosed, and show that the response is consistent with conventional radio antenna theory. The example first demonstrates the polarization effect, the suppression of the reflected signal when the electric field of the incoming radiation is polarized perpendicular to the nanotube axis. Next, the example demonstrates the interference colors of the reflected light from an array, and show that they result from the length matching antenna effect. This antenna effect could be used in a variety of optoelectronic devices, including THz and IR detectors.

[**0064**] In recent years, periodic and random arrays of multi-walled carbon nanotubes (MWCNTs) have been synthesized on various substrates, by the plasma-enhanced chemical vapor deposition (PECVD) process. Each nanotube in such arrays is a metallic rod of about 50 nm in diameter and about 200 to about 1000 nm in length. Therefore, one can view interaction of these arrays with the electromagnetic radiation as that of an array of dipole antennas. Since the most efficient antenna interaction occurs when the length of the antennas is of the order of the wavelength of the incoming radiation, the example expects an antenna-like interaction of MWCNT arrays with visible light. There are two major antenna effects. First, the polarization effect suppresses the response of an antenna when the electric field of the incoming radiation is polarized perpendicular to the dipole antenna axis. Second, the antenna length effect maximizes the antenna response when the antenna length is a multiple of half-wavelength of the radiation. The polarization antenna effort has already been observed in the Raman response of single-walled carbon nanotubes. The nanoscopic dipole antenna length effect was recently observed in microbolometer, stripline antenna. This example demonstrates both of these antenna effects in random MWCNT arrays. This example utilizes random nanotube arrays to suppress the intertube diffraction, which obscures the intratube antenna effects that are of interest here.

[**0065**] The MWCNT arrays of this example are fabricated using PECVD. The silicon substrate is coated with a thin film of nickel catalyst (about 20 nm) in a dc magnetron sputtering system, that is then heated to about 550-600 ° C. in a PECVD reaction chamber to break up the nickel film into small catalyst particles. A gas mixture NH_3 and C_2H_2 is introduced into the PECVD chamber at the ratio of 2:1, and a dc glow discharge plasma is then generated and maintained by a bias voltage of about 500-550V. A growth time of about 1-2 minutes yields nanotubes around or shorter than 1000 nm. FIG. **13**A shows the scanning electron microscope (SEM) image of such an array or random MWCNTs. By modifying the growth parameters, and/or the geometry of the bias voltage electrodes, a nonuniform growth of nanotubes, with average length varying across the sample, can also be achieved. This has been utilized to produce the samples used in the present example.

[**0066**] The example first demonstrates the polarization effect. A small piece of silicon wafer (2×1 cm^2) was coated with a thin film of Cr. Subsequently, one-half of the sample was coated with a thin film of Ni catalyst, and processed to grow a random array of MWCNTs. The sample was illuminated with white unpolarized light, and observed in a specular direction through a rotation polarizer. FIG. **14** shows that when the polarizer is oriented parallel to the growth direction of the nanotubes (orientation angle $\theta=0°$), the light reflected from the array is clearly visible, while the exposed metallic half of the sample is dark (not reflecting). With increasing (or decreasing) angle θ, intensity of the light reflected from the nanotube array diminishes, while the intensity reflected from the metallic side increases until at $\theta=90°$, the radiation is observable essentially only from the metallic side.

[**0067**] This behavior follows from the fact that, while in nanotubes currents are excited predominantly along their length, in the metallic film, currents flow in the film plane; that is perpendicular to the nanotubes. Each nanotube acts as an antenna reradiating light with the electric field E, polarized in the plane parallel to the antenna. A polarizer, with its axis of polarization rotated by an angle θ to this plane, transmits radiation with a projected electric field $E'=E\cos\theta$, and therefore the corresponding observed intensity is given by the law of Malus I_{NT} is proportional to $(E'')^2=E^2\cos^2\theta$ (solid line circles in FIG. **14**). For light reflected from the metallic film the situation is exactly "out-of-phase" with that of the array; that is, Imetal is proportional to $(E'')^2=E^2\sin^2\theta$ (dotted line-squares in FIG. **14**).

[**0068**] The second characteristic of an antenna is its resonant response behavior as a function of the radiation wavelength. This results from the condition that the induced current oscillations must "fit" into the antenna length (i.e., satisfy the boundary conditions at the antenna ends). A general equation describing the scattering maxima from a random array of dipole antennas (with vanishing current at each end) is:

$$L=m(\lambda/2)f(\theta,n), \tag{1}$$

where $f(\theta,n)=1$ for a single, simple diode, and $f(\theta,n)=(n^2-\sin^2\theta)^{-1/2}$ in the limit of the very dense array (thin film limit), where the average interantenna distance $D<\lambda$, $f(\theta,n)$ is equal to about 1., and is only weakly dependent on the angle θ. As such, similar behavior is expected for the random array of MWCNTs.

[**0069**] FIG. **15** shows a sample of random array of nanotubes with gradually reduced lengths (from left to right(illuminated by white light. The strong interference colors are due to the antenna length effect. FIG. **16** shows the intensity of the reflected light at the specular direction versus the radiation wavelength of the incoming radiation measured at selected spots (positions **A1**-**A7**) of the sample shown in

FIG. **15**. Experiments were done using the Ocean Optics USB2000 Fiber Optic Spectrometer (FOS). White light emerging from a 50-μm-diameter finer was focused onto the sample surface at about a 30 degree angle of incidence. Incident spot size was of the order of about 0.5 mm. A receiving fiber with a 1 mm diameter is positioned to collect light reflected spectrally from the sample surface. The system was first corrected for dark field and then normalized with respect to the tungsten light source and reflectance from the silicon substrate at the 30° incident angle. Another sample, with longer nanotubes, produced insufficient scattered light intensity for the FOS, and the wavelength was estimated using a high sensitivity CCD camera and optical filters, with accuracy of about 10%. The exact positions at which the data were acquired were permanently marked (scratched with a needle) on each of the samples. The SEM pictures were then used to estimate the average nanotube length at each marked spot. To minimize the parallax error of this estimate, only the collapsed (lying flat on the surface) nanotubes in the scratched area was measured.

[0070] In addition to the experiments described herein, computer simulations of the electromagnetic response from a random dipole antenna array have been performed. The array was modeled as a set of 10 parallel, equal-length antennas, randomly distributed on, and perpendicular to, a flat substrate. Antenna dimensions and the average interantenna distance represent the actual nanotube array. The dielectric constant of the substrate is assumed to be real and equal to 10. The resulting reflection curves for various antenna lengths are shown in FIG. **17**.

[0071] FIG. **18** combines the experimental and theoretical results to demonstrate the antenna length effect. In FIG. **18**, positions of the various reflected intensity maxima are plotted versus the corresponding average antenna length L. Solid lines represent the ideal dipole antenna condition [Eq. (1), with f=1] for different m. The measured results are represented as solid circles and squares. Crosses mark positions of the distinct maxima of the theoretical curves. Arrows indicate those maximas in FIG. **17**. It is clear that both experimental and theoretical results follow closely the ideal dipole antenna condition, and thus demonstrate that MWCNTs can act as light antennas.

[0072] This example also estimates the quality of the nanotube antennas. FIG. **17** shows a comparison between one of the experimental curves of FIG. **16** (for position A_5) shown as squares, and the corresponding calculated response. This comparison shows that the calculation, which assumed infinite conductivity of the metallic antenna, reproduces well the measured line width of the peak. Therefore, the peak width is primarily due to the radiation losses of currents induced inside the nanotubes. As such, this example concludes that the actual scattering rate of the conducting electrons (y) in the nanotube antenna must be much less that the width of the peak in FIG. **17**. After replotting the peak versus frequency (rather than the wavelength), the example finds that the width is about 10^{15s-1}, and therefore y must be of the order $1014s^{-1}$ or less. This is a very low scattering rate of the order of (or better than) that for good metals such as copper.

[0073] The fact that MWCNTs act as high quality light antenna suggests various applications based on the radio analogy. For example, a THz demodulator could be built, if a sufficiently fast diode is attached to (or built into) each antenna in the array mounted on a THz stripline. The modulating THz signal could then be seamlessly introduced into the stripline by shining modulated light onto the array. This scheme could be used in a new generation of THz and possibly IR detectors. The antenna length effect can be tuned by controlling the nanotube length, and to some extent the array density during the growth process, making the devices frequency selective. In principle, the antenna effects should be also detectable in, and the same applications possible with, arrays of aligned single-walled nanotubes. However, at this moment, no scheme for making such arrays of all metallic single-walled nanotubes exists, and there is no reason to believe that such a system would have any advantage over those based on MWCNTs.

[0074] In conclusion, this example demonstrates that MWCNTs interact with light in the same manner as simple diode radio antennas. In particular, they show both the polarization and the length antenna effect. The first effect is characterized by a suppression of the reflected signal when the electric field of the incoming radiation is polarized perpendicular to the nanotube axis. The second, the antenna effect, maximizes the response when the antenna length is a proper multiple of the half-wavelength of the radiation. These effects could be used in a variety of optoelectronic devices, such as THz and/or IR detectors.

[0075] All patents, patent applications, and published references cited herein are hereby incorporated by reference in their entirety. It will be appreciated that various of the above-disclosed and other features and functions, or alternatives thereof, may be desirably combined into many other different systems or applications. Various presently unforeseen or unanticipated alternatives, modifications, variations, or improvements therein may be subsequently made by those skilled in the art which are also intended to be encompassed by the following claims.

What is claimed is:

1. A solar cell comprising:

a planar substrate having a top side and a bottom side;

an at least one optical antenna comprising a geometric morphology capable of accepting energy;

a rectifier having the optical antenna at a first end and engaging the substrate at a second end wherein the rectifier comprises the optical antenna engaged to a rectifying material; and

a metal layer wherein the metal layer surrounds a length of the rectifier,

wherein the optical antenna accepts energy and converts the energy from AC to DC along the rectifier.

2. The cell of claim 1 wherein the geometric morphology of the optical antenna is a bow-tie morphology.

3. The cell of claim 1 wherein the geometric morphology of the optical antenna is a loop morphology.

4. The cell of claim 1 wherein the geometric morphology of the optical antenna is a spiral morphology.

5. The cell of claim 1 wherein the optical antenna comprises carbon nanotubes.

6. The cell of claim 1 wherein the optical antenna comprises an aluminum nanorod.

7. The cell of claim 1 wherein the optical antenna comprises a gold nanorod.

8. The cell of claim 1 wherein the rectifying material is a semiconductor.

9. The cell of claim 9 wherein the semiconductor is selected from the group consisting of doped silicon, undoped silicon, silicon carbide and GaAs.

10. The cell of claim 1 further comprising a plurality of optical antennas.

11. The cell of claim 10 wherein the plurality of optical antennas are of random lengths.

12. The cell of claim 10 wherein the plurality of optical antennas are of random orientation.

13. A solar cell comprising:

a planar substrate having a conductor layer below a semiconductor layer;

an array of carbon nanotubes engaging the semiconductor layer at a first end and comprising an optical antenna at a second end; and

a passivation layer wherein the passivation layer surrounds a length of the carbon nanotubes,

wherein the optical antenna accepts energy and delivers energy to the solar cell wherein AC is rectified to DC.

14. The cell of claim 13 wherein the passivation layer comprises a polymeric material.

15. The cell of claim 13 further comprising a transparent conductive layer above the passivation layer.

16. The cell of claim 15 further comprising a second passivation layer above the transparent conductive layer.

17. A method for producing a solar cell, comprising:

growing a plurality of vertically-aligned nanotubes on a substrate;

depositing a layer of a rectifying material onto the nanotubes; and

depositing a layer of metal to cover a length of the nanotubes.

18. The method of claim 17 wherein the nanotubes are carbon nanotubes.

19. The method of claim 17 wherein the rectifying material is a semiconductor.

20. The method of claim 17 wherein the rectifying material is selected from the group consisting of air, a vacuum, and an insulator.

Abstract

In this paper, the authors have presented a reduced size metamaterial loaded circular microstrip patch antenna. In the present work, complementary split ring resonator is loaded in the ground plane of circular microstrip patch antenna is. The unloaded circular microstrip patch antenna resonates at 6.11 GHz, whereas after loading it with complementary split ring resonator, the same antenna resonates near 6.11 GHz with reduced size. The effective footprint of the antenna is reduced by nearly 64% compared to the conventional patch antenna. The gain of the metamaterial loaded antenna structure is 5.04 dB.

Process and Apparatus for Converting Static Atmospheric Electrical Energy into Dynamic Electrical Energy of any Suitable High Periodicity

Abstract -- Atmospheric electricity, utilizing; influence machines.-Static atmospheric charges are converted into alternating-currents of any desired frequency by rotary machines, the stator and rotor elements of which form condensers having a capacity which varies during the revolution as described in Specincation 157,262. In the simplest form, Fig. 2, the curved stator plates 2, 1 are connected to earth E2 and the aerial A which collects the atmospheric charges and is earthed through a safety spark gap F. The rotor is motor-driven and consists of concentric plates 3, 4 joined through slip-,rings (not shown) to an inductance 9 shunted by a condenser 5. With a given aerial polarity, rotation of the plates 3, 4 causes current reversals on the circuit A, 1, 9, 2, E@, whereby oscillations are set upon the circuit 9, 5, these being tapped by leads 11, 12. The condenser 5 may consist of concentric tubes rotating with the rotor or of two juxtaposed wound spirals having capacity. The stator and rotor condenser plates may extend over nearly a semicircle in place of the quadrants shown in Fig. 2 and the rotor may comprise two consecutive cylindrical plates or coil condensers each divided into halves, the inner half of each being connected to the outer half of the other. Fig. 7 shows a form in which rings 1, 2, mounted in a casing comprising upper and lower parts insulated from each other, are connected to the stator condenser plates at intervals. The rotor plates 3, in equal number, are connected to slip-rings 5, 6 from which alternating-current is taken by brushes when the rotor is motor-driven. The rings 1, 2 are respectively connected to the aerial collector and earth E2. Several methods of grouping the stator-rotor condenser pairs and the components of the oscillating circuit are described. The oscillatory current in the rotor circuit may react through a transformer on the main charging current and two pairs of stator and rotor plates 1, 2, 3, 4, Fig. 13, may be employed arranged on diameters at right-angles, the oscillatory circuit in this case consisting of a mutual inductance 5 having capacity and a portion of an adjustable inductance 9 in the stator earth connector E2. By suitably proportioning the stator and rotor plates, 'resonance may be established, whereby undamped waves may be produced. In the form shown in Fig. 15, for high-frequency oscillations, the aerial A and earth wire are tapped at points between the stator plates 1, 2 and condensers 16, 18 which are joined through an inductance 9. The rotor current is conveyed to the power circuit 11, 12 through transformers 10, 10<a>. The members composing the stator and rotor plates may be slotted, as shown in Fig. 8, with holes 1 for attaching them to the frame, or they may have spiral slots in their surfaces. Alternatively, they may be formed by embedding spiral wires 3 in a vulcanite mass 1 so as to give a smooth surface as shown in Fig. 11.

EM Wave Energy Converter

Abstract -- Electromagnetic wave energy is converted into electric power with an array of mutually insulated electromagnetic wave absorber elements each responsive to an electric field component of the wave as it impinges thereon. Each element includes a portion tapered in the direction of wave propagation to provide a relatively wideband response spectrum. Each element includes an output for deriving a voltage replica of the electric field variations intercepted by it. Adjacent elements are positioned relative to each other so that an electric field subsists between adjacent elements in response to the impinging wave. The electric field results in a voltage difference between adjacent elements that is fed to a rectifier to derive d.c. output power. The element pairs may be arranged in a two-dimensional array to provide power conversion of randomly polarized electromagnetic waves, such as sunlight.

Radio Receiver Protection Arrangement

Abstract -- A receiver protection arrangement in which a voltage dependent on aerial voltage and a voltage dependent on aerial current are aggregated and applied to means responsive to a predetermined aggregate level to effectively short circuit the aerial lead. Additional means may be provided to dissipate energy in the input stage of a protected receiver to cause a reduced impedance to be reflected across the output of the protective arrangement.

Seismic Warning System Using RF Energy Monitor

Abstract -- The ambient broadband radio frequency field strength from broadcast stations is monitored (Figure 4) by periodic sampling (50, 52). A warning indication is provided if the field strength drops significantly. Drops in such field strength have been correlated empirically with the occurrence of seismic activity, usually several days later. Thus the indication serves as an early warning of an impending earthquake. In one preferred embodiment, a broadband, horizontal, very long monopole antenna (40) was connected to a rectifying and smoothing circuit (Figure 3) to provide a dc output proportional to the ambient rf field...

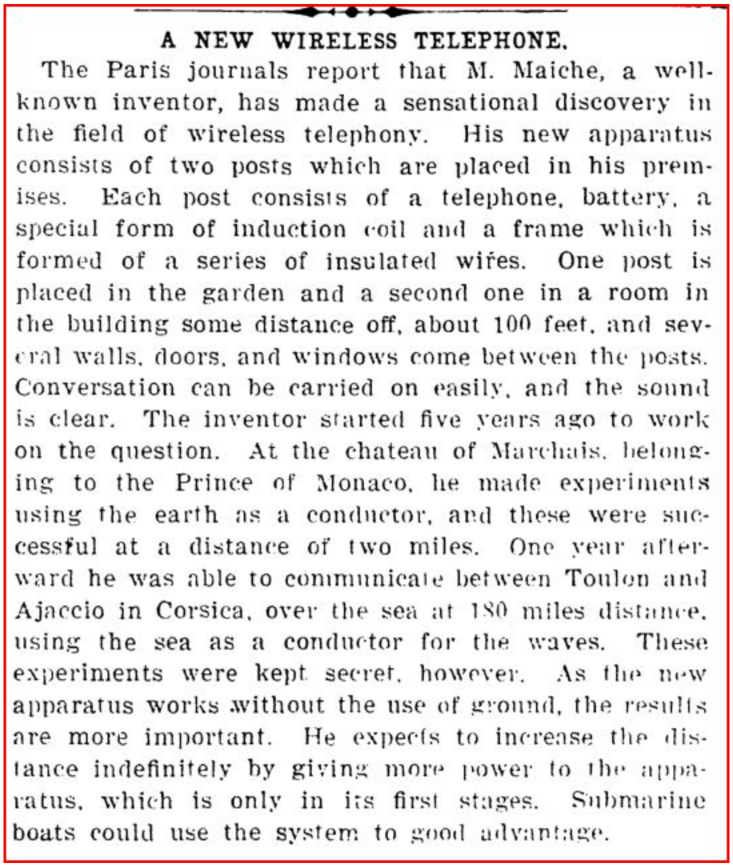
Sure, it looks silly now -- but wait until an EMP destroys the modern grid -- then you'll want/need this proven simple, inexpensive alt-tech earth-radio -- directional, low energy, & untappable -- and anyone can build it...

Jerry Vassilatos : Vril Compendium



A NEW WIRELESS TELEPHONE.

The Paris journals report that M. Maiche, a well-known inventor, has made a sensational discovery in the field of wireless telephony. His new apparatus consists of two posts which are placed in his premises. Each post consists of a telephone, battery, a special form of induction coil and a frame which is formed of a series of insulated wires. One post is placed in the garden and a second one in a room in the building some distance off, about 100 feet, and several walls, doors, and windows come between the posts. Conversation can be carried on easily, and the sound is clear. The inventor started five years ago to work on the question. At the chateau of Marchais, belonging to the Prince of Monaco, he made experiments using the earth as a conductor, and these were successful at a distance of two miles. One year afterward he was able to communicate between Toulon and Ajaccio in Corsica, over the sea at 180 miles distance, using the sea as a conductor for the waves. These experiments were kept secret, however. As the new apparatus works without the use of ground, the results are more important. He expects to increase the distance indefinitely by giving more power to the apparatus, which is only in its first stages. Submarine boats could use the system to good advantage.

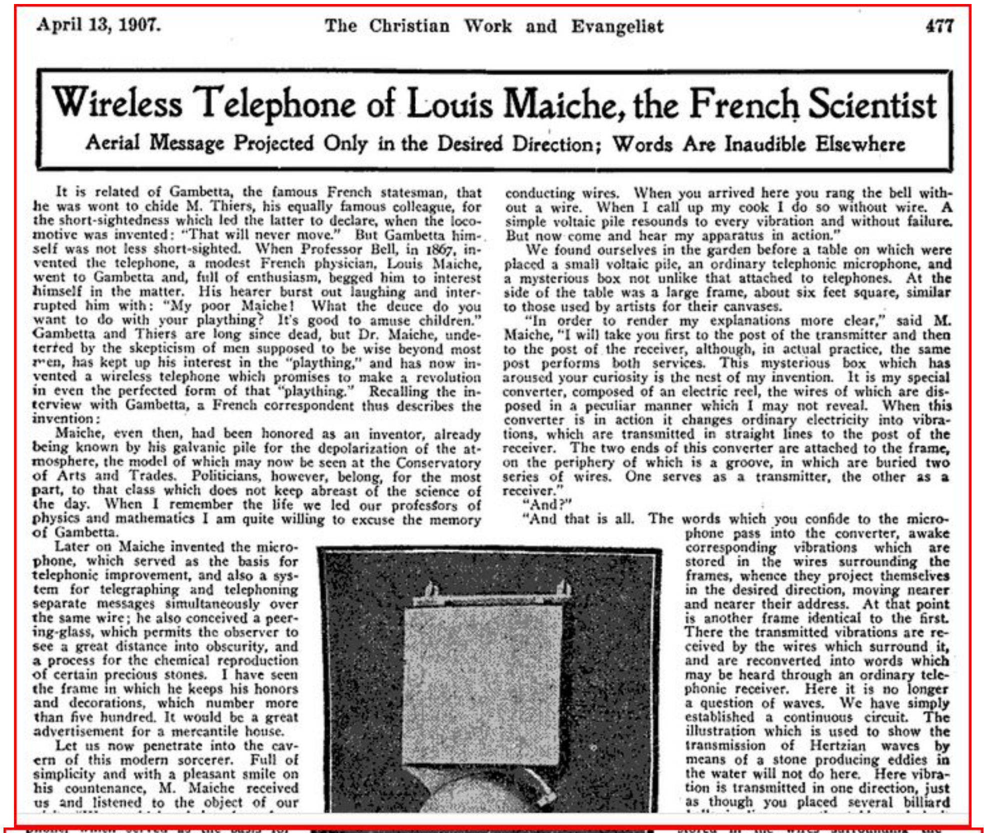
Wireless Telephone of Louis Maiche, the French Scientist



Wireless Telephone of Louis Maiche, the French Scientist

Aerial Message Projected Only in the Desired Direction; Words Are Inaudible Elsewhere

It is related of Gambetta, the famous French statesman, that he was wont to chide M. Thiers, his equally famous colleague, for the short-sightedness which led the latter to declare, when the locomotive was invented: "That will never move." But Gambetta himself was not less short-sighted. When Professor Bell, in 1867, invented the telephone, a modest French physician, Louis Maiche, went to Gambetta and, full of enthusiasm, begged him to interest himself in the matter. His hearer burst out laughing and interrupted him with: "My poor Maiche! What the deuce do you want to do with your plaything? It's good to amuse children." Gambetta and Thiers are long since dead, but Dr. Maiche, undeterred by the skepticism of men supposed to be wise beyond most men, has kept up his interest in the "plaything," and has now invented a wireless telephone which promises to make a revolution in even the perfected form of that "plaything." Recalling the interview with Gambetta, a French correspondent thus describes the invention:

Maiche, even then, had been honored as an inventor, already being known by his galvanic pile for the depolarization of the atmosphere, the model of which may now be seen at the Conservatory of Arts and Trades. Politicians, however, belong, for the most part, to that class which does not keep abreast of the science of the day. When I remember the life we led our professors of physics and mathematics I am quite willing to excuse the memory of Gambetta.

Later on Maiche invented the microphone, which served as the basis for telephonic improvement, and also a system for telegraphing and telephoning separate messages simultaneously over the same wire; he also conceived a peering-glass, which permits the observer to see a great distance into obscurity, and a process for the chemical reproduction of certain precious stones. I have seen the frame in which he keeps his honors and decorations, which number more than five hundred. It would be a great advertisement for a mercantile house.

Let us now penetrate into the cavern of this modern sorcerer. Full of simplicity and with a pleasant smile on his countenance, M. Maiche received us and listened to the object of our

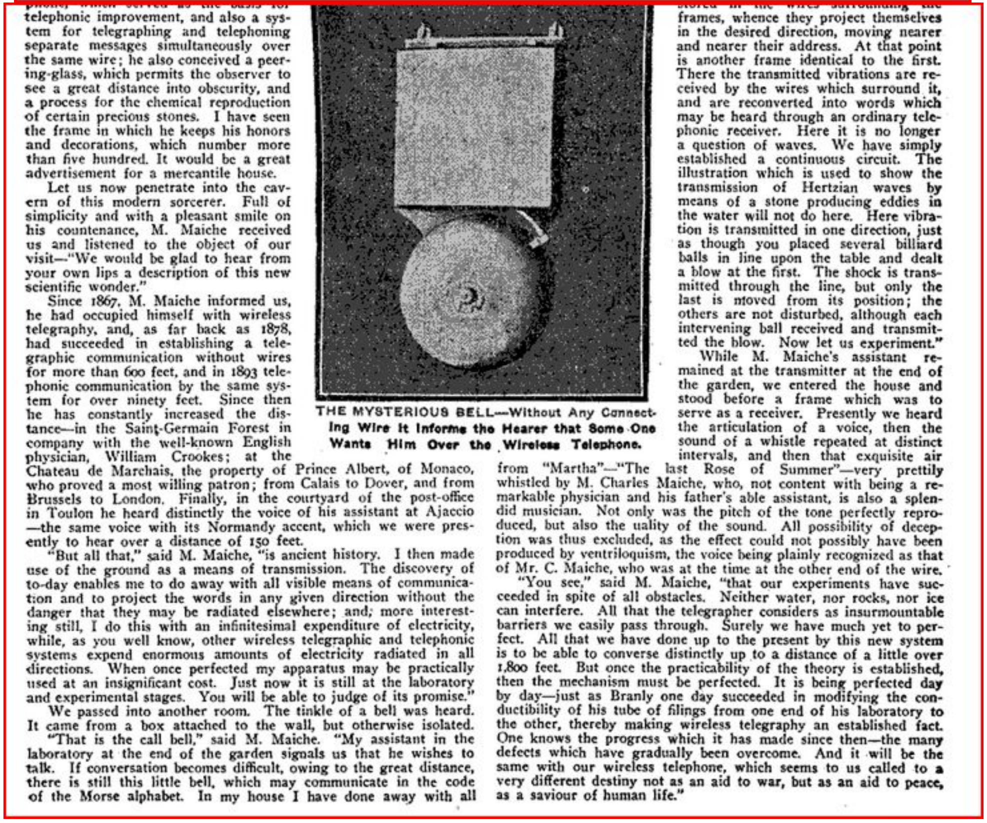
conducting wires. When you arrived here you rang the bell without a wire. When I call up my cook I do so without wire. A simple voltaic pile resounds to every vibration and without failure. But now come and hear my apparatus in action."

We found ourselves in the garden before a table on which were placed a small voltaic pile, an ordinary telephonic microphone, and a mysterious box not unlike that attached to telephones. At the side of the table was a large frame, about six feet square, similar to those used by artists for their canvases.

"In order to render my explanations more clear," said M. Maiche, "I will take you first to the post of the transmitter and then to the post of the receiver, although, in actual practice, the same post performs both services. This mysterious box which has aroused your curiosity is the nest of my invention. It is my special converter, composed of an electric reel, the wires of which are disposed in a peculiar manner which I may not reveal. When this converter is in action it changes ordinary electricity into vibrations, which are transmitted in straight lines to the post of the receiver. The two ends of this converter are attached to the frame, on the periphery of which is a groove, in which are buried two series of wires. One serves as a transmitter, the other as a receiver."

"And?"

"And that is all. The words which you confide to the microphone pass into the converter, awake corresponding vibrations which are stored in the wires surrounding the frames, whence they project themselves in the desired direction, moving nearer and nearer their address. At that point is another frame identical to the first. There the transmitted vibrations are received by the wires which surround it, and are reconverted into words which may be heard through an ordinary telephonic receiver. Here it is no longer a question of waves. We have simply established a continuous circuit. The illustration which is used to show the transmission of Hertzian waves by means of a stone producing eddies in the water will not do here. Here vibration is transmitted in one direction, just as though you placed several billiard



telephonic improvement, and also a system for telegraphing and telephoning separate messages simultaneously over the same wire; he also conceived a peering-glass, which permits the observer to see a great distance into obscurity, and a process for the chemical reproduction of certain precious stones. I have seen the frame in which he keeps his honors and decorations, which number more than five hundred. It would be a great advertisement for a mercantile house.

Let us now penetrate into the cavern of this modern sorcerer. Full of simplicity and with a pleasant smile on his countenance, M. Maiche received us and listened to the object of our

visit—"We would be glad to hear from your own lips a description of this new scientific wonder."

Since 1867, M. Maiche informed us, he had occupied himself with wireless telegraphy, and, as far back as 1878, had succeeded in establishing a telegraphic communication without wires for more than 600 feet, and in 1893 telephonic communication by the same system for over ninety feet. Since then he has constantly increased the distance—in the Saint-Germain Forest in company with the well-known English physician, William Crookes; at the Chateau de Marchais, the property of Prince Albert, of Monaco, who proved a most willing patron; from Calais to Dover, and from Brussels to London. Finally, in the courtyard of the post-office in Toulon he heard distinctly the voice of his assistant at Ajaccio—the same voice with its Normandy accent, which we were presently to hear over a distance of 150 feet.

"But all that," said M. Maiche, "is ancient history. I then made use of the ground as a means of transmission. The discovery of to-day enables me to do away with all visible means of communication and to project the words in any given direction without the danger that they may be radiated elsewhere; and, more interesting still, I do this with an infinitesimal expenditure of electricity, while, as you well know, other wireless telegraphic and telephonic systems expend enormous amounts of electricity radiated in all directions. When once perfected my apparatus may be practically used at an insignificant cost. Just now it is still at the laboratory and experimental stages. You will be able to judge of its promise."

We passed into another room. The tinkle of a bell was heard. It came from a box attached to the wall, but otherwise isolated.

"That is the call bell," said M. Maiche. "My assistant in the laboratory at the end of the garden signals us that he wishes to talk. If conversation becomes difficult, owing to the great distance, there is still this little bell, which may communicate in the code of the Morse alphabet. In my house I have done away with all

THE MYSTERIOUS BELL—Without Any Connecting Wire It Informs the Hearer that Some One Wants Him Over the Wireless Telephone.

frames, whence they project themselves in the desired direction, moving nearer and nearer their address. At that point is another frame identical to the first. There the transmitted vibrations are received by the wires which surround it, and are reconverted into words which may be heard through an ordinary telephonic receiver. Here it is no longer a question of waves. We have simply established a continuous circuit. The illustration which is used to show the transmission of Hertzian waves by means of a stone producing eddies in the water will not do here. Here vibration is transmitted in one direction, just as though you placed several billiard

balls in line upon the table and dealt a blow at the first. The shock is transmitted through the line, but only the last is moved from its position; the others are not disturbed, although each intervening ball received and transmitted the blow. Now let us experiment."

While M. Maiche's assistant remained at the transmitter at the end of the garden, we entered the house and stood before a frame which was to serve as a receiver. Presently we heard the articulation of a voice, then the sound of a whistle repeated at distinct intervals, and then that exquisite air from "Martha"—"The last Rose of Summer"—very prettily whistled by M. Charles Maiche, who, not content with being a remarkable physician and his father's able assistant, is also a splendid musician. Not only was the pitch of the tone perfectly reproduced, but also the uality of the sound. All possibility of deception was thus excluded, as the effect could not possibly have been produced by ventriloquism, the voice being plainly recognized as that of Mr. C. Maiche, who was at the time at the other end of the wire.

"You see," said M. Maiche, "that our experiments have succeeded in spite of all obstacles. Neither water, nor rocks, nor ice can interfere. All that the telegrapher considers as insurmountable barriers we easily pass through. Surely we have much yet to perfect. All that we have done up to the present by this new system is to be able to converse distinctly up to a distance of a little over 1,800 feet. But once the practicability of the theory is established, then the mechanism must be perfected. It is being perfected day by day—just as Branly one day succeeded in modifying the conductibility of his tube of filings from one end of his laboratory to the other, thereby making wireless telegraphy an established fact. One knows the progress which it has made since then—the many defects which have gradually been overcome. And it will be the same with our wireless telephone, which seems to us called to a very different destiny not as an aid to war, but as an aid to peace, as a saviour of human life."

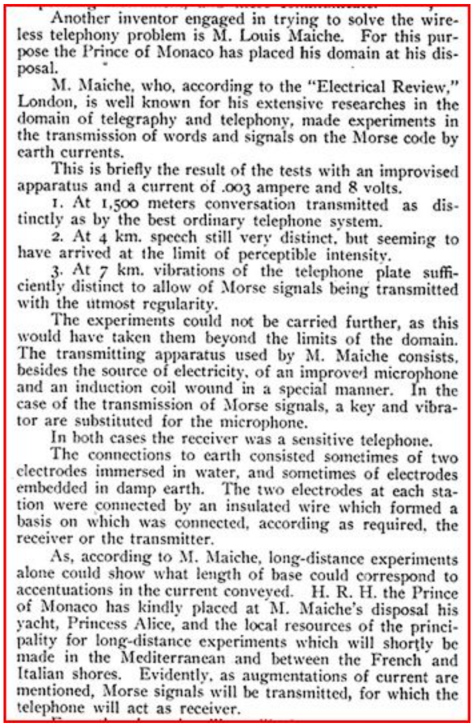
Telephony, Volumes 3-4



Another inventor engaged in trying to solve the wireless telephony problem is M. Louis Maiche. For this purpose the Prince of Monaco has placed his domain at his disposal.

M. Maiche, who, according to the "Electrical Review," London, is well known for his extensive researches in the domain of telegraphy and telephony, made experiments in the transmission of words and signals on the Morse code by earth currents.

This is briefly the result of the tests with an improvised apparatus and a current of .003 ampere and 8 volts.

1. At 1,500 meters conversation transmitted as distinctly as by the best ordinary telephone system.

2. At 4 km. speech still very distinct, but seeming to have arrived at the limit of perceptible intensity.

3. At 7 km. vibrations of the telephone plate sufficiently distinct to allow of Morse signals being transmitted with the utmost regularity.

The experiments could not be carried further, as this would have taken them beyond the limits of the domain. The transmitting apparatus used by M. Maiche consists, besides the source of electricity, of an improved microphone and an induction coil wound in a special manner. In the case of the transmission of Morse signals, a key and vibrator are substituted for the microphone.

In both cases the receiver was a sensitive telephone.

The connections to earth consisted sometimes of two electrodes immersed in water, and sometimes of electrodes embedded in damp earth. The two electrodes at each station were connected by an insulated wire which formed a basis on which was connected, according as required, the receiver or the transmitter.

As, according to M. Maiche, long-distance experiments alone could show what length of base could correspond to accentuations in the current conveyed. H. R. H. the Prince of Monaco has kindly placed at M. Maiche's disposal his yacht, Princess Alice, and the local resources of the principality for long-distance experiments which will shortly be made in the Mediterranean and between the French and Italian shores. Evidently, as augmentations of current are mentioned, Morse signals will be transmitted, for which the telephone will act as receiver.

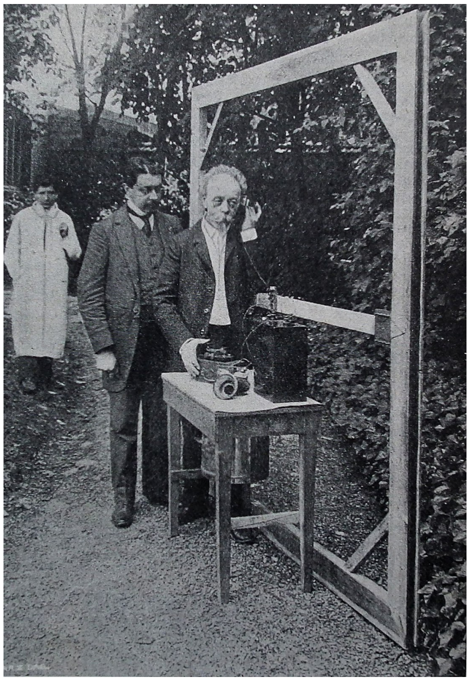
The world's first "mobile" phone (in 1906)

French inventor Louis Maiche and his wireless phone, arguably also the world's first mobile phone.
Image published in the Swedish weekly Hvar 8 Dag in September 1906 (Click to enlarge)



"M. Louis Maiche is the inventor of the wireless telephone and, like many scientists, is not so famous as he ought to be".

That is how an article in the Auckland Star on March 6, 1907, introduced the French inventor Louis Maiche, who also could be called the inventor of a mobile phone.

In the article M. Maiche describes how it all began:

"My first trials took place in 1867, but they were concerned more with wireless telegraphy, and it was not until 1893 that I exchanged a conversation through a wireless telephone at a distance of 30 yards."

Two months earlier, the New York Times had also published an article on M. Maiche and his wireless telephone invention. In the article the inventor refers to his successful experiments with telegraphy and then describes his work with the wireless telephone:

"I then made use of the ground as a means of transmission. The discovery of today enables me to do away with all visible means of communication and to project the words in any given direction without the danger that they may be radiated elsewhere; and, more interesting still, I do this with an infinitesimal expenditure of electricity, while, as you well know, other wireless telegraphic and telephone systems expend enormous amounts of electricity radiated in all directions."

"When once perfected my apparatus may be practically used at an insignificant cost. Just now it is still at the laboratory and experimental stages."

"You see", said M. Maiche,"that our experiments have succeeded in spite of all obstacles. Neither the water, nor rocks, nor ice can interfere. All that the telegrapher considers as insurmountable barriers we easily pass through. Surely we have much to perfect! All that we have done up to the present is to be able to converse distinctly up to a distance of a little over 1,800 feet. But once the practicality of the theory is established, then the mechanism must be perfected."

"It is being perfected day by day - just as Branly one day succeeded in modifying the conductibility of his tube fillings from one end of his laboratory to the other, thereby making wireless telegraphy an established fact. And it will the same with our wireless telephone,which seems to us called to a very different destiny, not as aid to war, but as an aid to peace, as a savior of human life."

In the Auckland Star article M. Maiche gives some examples of the future use of his wireless telephone:

"Imagine two steamers steering through a fog. With my little apparatus the captain can tell the direction the other ship is taking. In case of an accident to a submarine my apparatus would enable the crew in danger to communicate with the convoying tug without fearing the breaking of a line as in the case of a telephone buoy. Miners entombed after a disaster like that at Courrieres could communicate with the rescue party. Two army corps making a night attack could keep in constant touch without risk of interruption. The ordinary citizen could have it in his drawing room, and would no longer be dependent upon the vagaries of the telephone exchange."

Both articles also include some technical descriptions of the use of M. Maiche's new wireless phone. It is possible that the French inventor's theories were not as successful as he himself thought. Otherwise it is difficult to understand why this page (in French) is the only one with information about him that I have been able to locate. Still, his concept of wireless (and mobile) telephony should merit him a place in the hall of fame of modern communication technology .

Patents

Nouveau mode de transmission et de réception sans fil des signaux électriques

FR335990

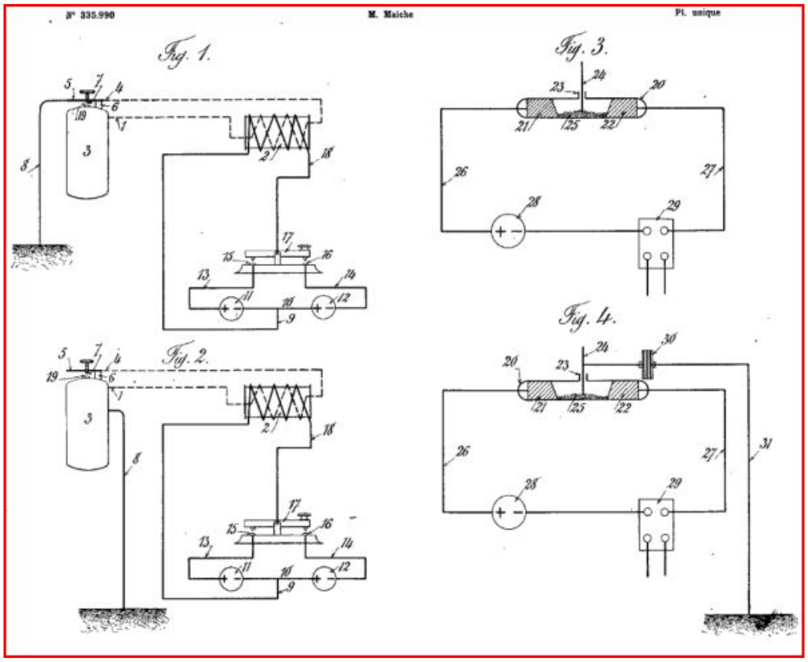
1904-02-22

The object of the present invention is a new method of transmitting and receiving wireless electrical signals. The essential means on which is based the system is the production transmits position and uses the position receiver electricity manifested in a new form which may be referred to as "electrostatic vibration" and is obtained as will be explained further by modification of a spark inductor. One of distinctive characters of this new manifestation of electricity is that it can be transmitted in space without the aid antennas and ground at all distances, and, in the same form as sound, light and heat, that is to say without poles.

The inductor being communicated c with a power source, a battery, for example, and a special switch which will be described below, each interruption is to be born in the armature current giving a spark, and it is the latter that is transform an "electrostatic vibration." The armature out of the coil wire after the last winding outside, is for this purpose connected to a large metal surface which can be exposed to air. This surface may be constituted either by c a hollow or solid cylinder or by one or more sheets of iron, copper or any other metal usual more or less thick. The surface is preferably rounded at the corners or packed with a border all around to remove spikes, as in the conductive electrostatic machines. It should be about one square meter per watt of the current flowing in the inductor. The other end of the armature is connected to an adjusting screw of which the tip k of platinum or gold is next to a button, also in a gold or platinum, carried on the large surface.

FIGS. 1 and 2 of the accompanying drawings show two provisions which may be 5 h adopted for the preparation of the transmitter station.

FIGS. 3 and k show two provisions and receiver.



One end of the armature wire of the coil -j is connected to the cylinder 3 rounded at its ends, and the end k of the wire is connected to plate 5 mounted on the insulating support 6 which is fixed to the cylinder 3 . The plate 5 is traversed by a setscrew 55 provided beyond tip 7 made of gold or platinum. The end of the induced wire k is that by which begins rolling on a bobbin. Wire 8 communicates with the earth or the plate 5 (Fig. I) is the cylinder 3 (Fig. A).

Improvements in and relating to Electric Transformers.
GB190727157

1908-10-29

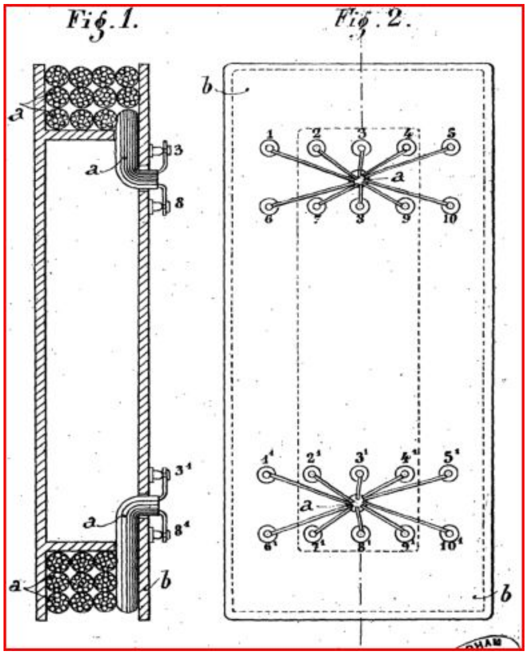
Comprises a large number of windings wound in the form of a cable a on a coreless frame b, and led out to terminals 1 ... 10 and, adapted to be connected in quantity or tension by means of a commutator so that three or more independent circuits may be made.

COMPLETE SPECIFICATION.

The present invention relates to electric transformers of the class described by Specifications Nos. N;821901 (Amberg), z1854 (Swinburne), and 4/I83 (Clerc) and it particularly concerns the arrangement of the windings.

The invention is represented in the accompanying drawings;-

Figs. 1 and 2, show a section and a front view respectively of the improved transformer.



The transformer which has no magnetic core, is merely constituted by a convenient number of insulated wires, 10 for example, which are united to form a cable a which is wound around a frame b. The ends of the cable project through two holes of the frame and the ends of each wire are joined to terminals 1 to 10 and 11 to 101 respectively. In the drawings are shown 20 terminals, the first ten of which correspond to the beginnings of the 10 wires, and the other ten correspond to the ends of the same wires.

Thus, a winding of a certain number of identical wires is obtained which are all wound parallel and simultaneously and which may be connected by means of a commutator so as to form groups to 'be varied according to requirement; so that there are thus constituted three or more circuits which are entirely independent the one of the other and the length of which can be varied at will.

By conveniently joining the free ends of some of the wires, a primary winding of weak resistance is obtained with the wires of same joined for quantity, while one or more of the secondary windings are joined for tension, thus providing any required resistance.

The construction of the transformer by means of a great number of separate wires offers numerous advantages amongst which are the facility of connecting the separate wires at will to constitute the circuits; the arrangement enabling a supplementary circuit to be branched off at any point of the said circuits; and the reciprocal independence of these circuits with large number.

Improvements in and relating to Electric Transformers.
GB190721535

1908-05-28

Transformers for telegraphy and wireless telegraphy are made without a magnetic core, and of little depth but of large diameter. They have the primary winding e enclosed within the secondary winding c, g, but separated therefrom by insulation d, f. The windings may be formed in sections, and coupled up in any order by means of a commutator.

COMPLETE SPECIFICATION.

This invention relates to electric transformers the construction of which is improved so that currents of induction of very short periodicity are obtained.

The currents, the duration of which is extremely short, possess special properties which are particularly useful when applied in telegraphy and in wireless telephony.

Transformers without magnetic core and with the secondary winding wound around the primary, or with the primary winding enclosed within insulating material round wh,ich is wound the secondary winding so that the whole forms a cable, have been provided, and my invention is limited to the form and construction of the transformer as hereinafter set forth.

My improved electric transformer contains its primary wire within a cable of the secondary wires in the form of a single coil of little thickness but of very large dia,meter, said coil or cable being applied to a ring-shaped transformer body.

The accompanying drawing shows my improved electric transformer.

Fig. 1 is a section on line A-B of Fig. 2 and

Fig. 2 is a plan of the ring-shaped transformer.

Fig.1.

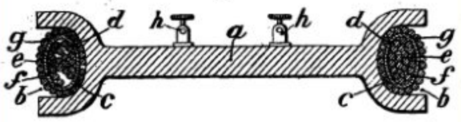


Fig.2.

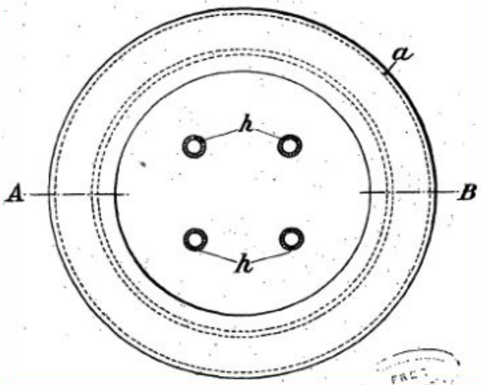


As will be seen from the drawings, the transformer a is of comparatively large diameter which may be several meters. In the drawing the transformer is represented of circular cross-section, it could however be of square or other cross-section. This transformer is very short because all the wires of the winding are located on its periphery in an appropriate hollow or groove b. For manufacturing the trans-former I place around the rim of this kind of wheel or dial: a, a first layer of secondary wire which is covered by a suitable insulator d and upon this insulator the primary wire e is wound which is covered by another layer of insulating material f. The two insulating layers d and f are connected in such a manner that the primary wires e are well insulated, and the coil is then finished by applying an outer winding of secondary wire g, the latter surrounding the primary in such a manner as to form a cable. In this manner a ring of large diameter is obtained which is composed of the secondary wires c, g which enclose a core of suitably insulated and wholly surrounded primary wires e and which ring is applied to a ring-shaped transformer-body having a peripheral groove of suitable cross-section.

The apparatus comprises four terminals h, two of which serve for fixing the ends of the secondary wires, the other two serving for fixing the ends of the primary winding.
There could be arranged several independent cables or rings in each of which the secondary wires entirely surround the primary wires and in such case each of the terminals would be replaced by a multiple commutator permitting to join up the different secondary wires as well as the different primary wires either for tension or for quantity according to the effect to be obtained.

Improvements in connection with Wireless Telegraphy and Telephony.
GB190721252

1907-11-21

The transmitting and receiving circuits at one station for an inductive system of telephony or telegraphy are arranged as shown. A coil a, consisting of a few turns of thick wire, is used alone in transmitting, but is connected in series with a coil b, consisting of a large number of turns of fine wire, for receiving; the circuit of the coil b is broken automatically, during transmission, by means of a Morse key c. The circuit of the coil a includes a battery n and a microphone o for telephony, or an interrupter for telegraphy, and the coil b is connected with a telephone h.

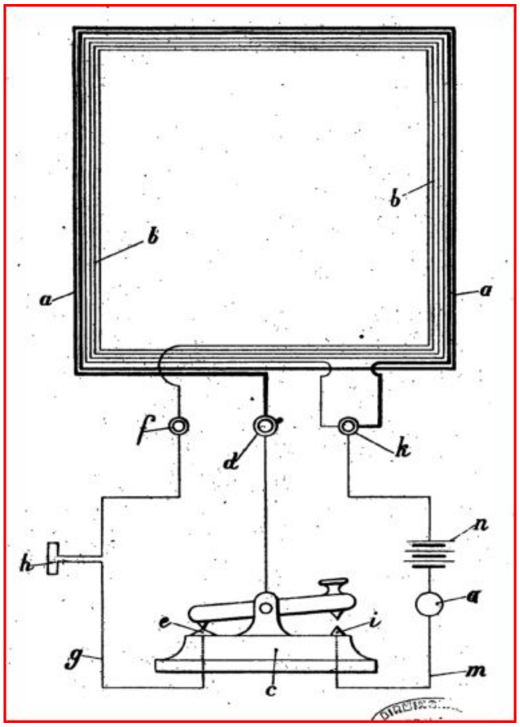
There are known systems for telegraphy and telephony without connecting wires which utilise, instead of Hertzian waves, the phenomena of distant induction by means of electric vibrations of very short duration, but great amplitude. With such systems, one and the same winding is used fur sending and for receiving; for sending it is placed in circuit with a source of electricity (battery, accumulator, etc.) and with a microphone or an interrupter destined to produce the vibrations in question. The same winding is placed in circuit with a .receiving telephone .for receiving the currents which arc induced at a. distance from the sending winding of the other station.

It is obvious that this single coil cannot equally well serve for the sending as for the receiving. To transmit well it ought to be made from thick and short wire, whilst for receiving well it ought to be of long and thin wire.

It would evidently be the simplest to provide each station with two different coils of which one serves as transmitter and the other as receiver, but lucre is another difficulty to be considered; for receiving, the long and thin coil has to be closed by the telephone and in that condition it would absorb nearly all the energy which ought to be sent out by the transmitter.

The present invention rotates to a special method of mounting the parts constituting a station in order to overcome the above mentioned difficulty; besides, the special method of mounting permits to join the two coils one behind the other for receiving whereby the receiving power of the station is considerably increased.

The accompanying drawing represents diagrammatically a station according to the present Invention.



a is the inductor wire which serves fur transmitting; this wire is thick and relatively short. b is the induced winding for receiving the induced vibrations from the inductor winding of the transmitting station; this winding consists of thin wire of considerable length. c is a. Morse-manipulator the lever of which is connected through the contact let with one end of wire a, its connector e is through the contact f connected with one of the ends of wire; the wire g which connects the contact f with wire b comprises the telephonic receiver h ;the other connector i of the Morse apparatus is connected through terminal with the free ends of the two wires a and b which are joined at this point. The connecting wire m which serves for this purpose, comprises the battery n and the microphone o.

It is easily' understood that in the inoperative position of the Morse key (as represented in the drawings) the two coils and b form one circuit closed on the telephone h. This position is the receiving position. For transmitting, the key is depressed and brought in contact with the connector whereby the coil b is opened whilst the coil a is closed on the microphone and the battery.

It is to be understood, that the station described serves for the transmission of sounds. For the transmission of telegraphic signals, the microphone o is replaced by a suitable interruptor-vibrator and the apparatus is operated through the Morse key as usual.

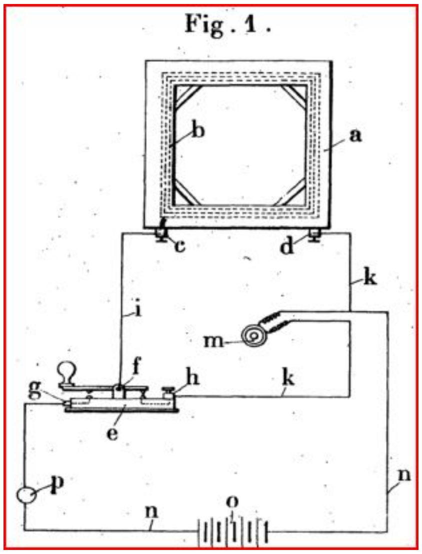
Improvements in and relating to Inductive Telegraphy and Telephony.
GB190712529

1908-03-12

In a system of telegraphy or telephony by magnetic induction, the coils are placed vertically and the same coil is used for transmitting and receiving. The coil b is wound on a frame a of any suitable shape, which may be lined with iron. One terminal of the coil b is connected to a key f, one contact of which is connected through a microphone p and battery o to the other terminal d of the coil. A telephone m is connected across the terminals of the coil through another contact of the key f, and its circuit is normally completed for receiving telephonic or telegraphic messages. Telegraphy is effected by manipulating the kev f to complete the circuit of battery o ; to telephone, the key is depressed and the microphone p is utilized. A high-frequency alternator may be used instead of the battery o, and a screen composed of sheets of paper soaked in paraffin, varnish, or glue may be placed behind the frame.

The present invention relates to improvements in that class of magnetic induction telegraphy and telephony in which transmission is effected between similar coils of wire at the receiving and transmitting stations. The invention is characterized by the fact that senders and receivers.are reversible, the member for transmitting the waves being the, same as the member which receives the waves.

In the drawing, a diagram of a station according to the present system is represented.



The transmitter and receiver for the electric waves consists of a. wooden frame (a) of fairly large dimensions; for example 4 meters square for a distance of 20 kilometers. In the drawing the frame is shown as being square but it may be of any other geometric shape having as center a.rectangle a lozenge, a circle, etc. The wall of the frame is provided with a groove (b) in which an insulated conducting wire is placed which is connected with the terminals (c) and (d). This wire is wound a. varying number of times around the frame so that it is of sufficient length according to the power of transmission required of the apparatus.

The frame (a) must be of sufficiently large dimensions to prevent the currents generated in opposite directions in the sides of the frame from tending to neutralise each other.

Each station comprises besides a Morse manipulator (e), the commutator of which is connected with one of the terminals (c) of frame (a) through the wire, its terminals (r) and (h) being connected with the other terminal (d) of frame (a).

An ordinary telephonic receiver (m) is inserted in, the circuit (k) which leads from the terminal (h.) of the manipulator to the frame, and in the other circuit (n), connecting the terminal (g) of the manipulator with. the frame, a battery (o) is inserted near the frame and , microphone (p) is inserted near the manipulator.

When the manipulator (c) is at rest (position shown in the drawing) the station is ready to receive the transmissions, the electric circuit (a, c, i, f, m, k, d, a) enclosing the frame and the telephone -being closed. One has only to hold the telephone to the ear to perceive all the currents which a.re induced in the frame (a).

The telephone (m) is put out of circuit when the commutator (f) is pressed down, whilst t.he circuit will be closed upon the frame (a.) and battery (o). The station has thus become 11 sender, the battery sending variable currents into the frame according to the nature of the transmission to be effected. To telegraph according to the Morse alphabet one manipulates the commutator (f) in the usual manner, the telephone (m) of the other station permitting to distinctly perceive the dots and dashes. The operator simply gives one contact for the dot and two contacts following in quick succession for a dash. In this case the microphone (p) is superfluous but it does not disturb. When however one wants to telephone, the contact (g) has to be kept closed and one speaks in front of or into the microphone (p); the telephone (in.) of the other station will reproduce the sounds.

The source of electricity (o) can be a battery or an electro-magnetic generator giving alternating currents of high frequency. The currents which are thus sent into the frame (a) of the sender station have no appreciable effect upon the telegraphic receivers which could be provided at this station; they even do not influence the magnet needle owing to their **illst,nntfmeousness.**

To establish the communication between two stations the two frames (a) have to be placed in parallel planes, perpendicular to the line which would connect their centers, which can be effected through various means. The action (if the one of the frames on the other is effected through any obstacles whatsoever, no earth connection or air connection being necessary.

The reciprocal action of the frames can be increased through lining the bottom of groove (b) for its entire length with soft sheet iron, the lining being continuous or interrupted. The frame will thus become a kind of electro-magnet, the proportion of which are just the reverse of those generally used.

To communicate at very great distances several frames (n,) are joined up, the wires being joined up in series or for tension.

The efficiency can be considerably increased and the direction of transmission localised in avoiding dispersion at the sides or behind the frame, by means of a thick screen composed of superposed sheets of paper soaked in paraffn ; the paper could also be impregnated with varnish, glue or any other equivalent material.

Improvements in and relating to Telegraphic and Telephonic Systems.
GB190126600

1902-11-06

Relates to the arrangements of circuits in telegraph and telephone systems. In Fig. 1, a microphone b is shown in a main line a, and at the receiving-station is connected to the middle of a split battery f, g, two receivers l, m being connected between battery and earth. When induction coils are employed, two separate primaries take the place of the receivers in the Figure, and the receiver employed is placed in a common secondary. In another modification, the transmitter is bridged across two parallel closed circuits, including primaries and batteries, the secondary forming the line circuit.

This invention relates to telegraphic and telephonic systems and has for its object certain improvements hereinafter more particularly referred to and finally pointed out in the claims.

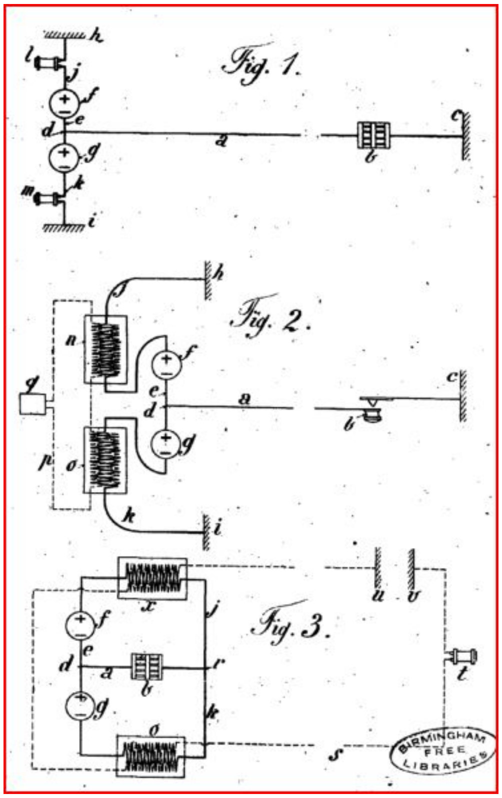
As is well known, in order to prevent over-heating of' the receiving and transmitting apparatus in telephonic or telegraphic installations it is necessary to prevent very strong current passing over them. It may however, in certain cases, be necessary to provide currents of varying energy within rather large limits, and this invention has for its object to provide a simple device which will permit currents of any force being passed through telegraphic and telephonic apparatus without the slightest risk of deterioration to such apparatus.

In order that my invention may be readily understood and carried into effect I will now proceed to describe the same fully with reference to the accompanying drawings wherein are shewn diagrammatically several methods of carrying my. invention into practice.

In the drawings :

Figure 1 shows the principle of my improved arrangement, and

Figures 2. and 3 are modified arrangements.



My improved system consists essentially of a line a of any convenient length in which is interpolated a microphone b or other appropriate transmitting apparatus. One end of this line is grounded at c and the other end is connected at d to.a wire e adapted to place into communication the opposite poles of the two sources of electricity of equal power, which for greater clearness sake I have represented as two single batteries f and g. These two batteries are respectively connected to earth at h and i. In the earth wires j and k are interpolated telegraphic or telephonic receivers l, m, of any convenient construction. In the example shown in the drawing the receivers and m are indicated as being telephonic receivers.

Having thus described the general arrangement of the system I will now explain the function of the various apparatus of the system.

Presuming that the wire a is non-existent and that the communication of the battery f and g with the earth has been established, a current passes from the positive pole of the battery f to earth through the wire then back .through the wire k, battery 9 and finally through the wire e to the negative pole of the battery f. Thus a closed circuit is established. Admitting now the wire a to be connected to the wire e at d and the transmitter b operated, the single current generated in the previous case will be replaced, by two currents which circulate in the same direction.

One of these currents starts from the positive pole of the battery f through the wire through earth from h to c through the transmitter b, wire a and wire e to the negative pole of the battery f.

The other current starts from the positive pole of the battery 9 through the 'wires e and a, the transmitter b, through earth from c to i and wire k to the negative pole of the battery g.

It will thus be seen that the wire a and transmitter b are simultaneously traversed by two equal currents in inverse directions.

In Figure 2 I have shown a telegraphic transmitter or key b but the general arrangement of the system is the the same as that previously described with the exception that the wires j and k form the primary conductors of the transformers n and o. The secondary conductor p, which is common to both transformers, leads,to the receiving apparatus q, for example a telegraphic receiving instrument.

Each contact ejected with the key b produces, as before explained a double derivation acting by subtraction of intensity upon the two transformers n and o, produces an induced current which is reproduced in totality in the receiving apparatus q. In the case of telephonic transmission the key must be replaced by a microphone as shown in Figure 1, while further the receiver q would also be a telephonic receiver.

By extending the same principle I can, as indicated in Figure 3, replace the two earth wires by two conductors and k joined together at r after having traversed the transformers x and o. The induced current may then be conveyed to the receiving instrument t over two lines, or as in the previous example over a line s and two earth connections u and v, placed more or less apart from each other.

It will be noticed that the microphone b forms part of the neutral conductors.

It acts exactly as in Figure 1. The differences of resistance produced by its vibrations influence the two coils x and o, and it is easy to understand that, whatsoever may be the intensity of the two electric sources f and g, the microphone is never exposed to the risk of becoming overheated for the reason that it is traversed by two equal currents in opposite directions.

It will thus be understood that the transmissions will be rendered perceptible in the receivers through the differences of intensity of the electric current; the differences being due to the differences of resistance of the neutral conductor which, in receiving two equal currents in opposite directions, is not much affected itself.

Improvements relating to the Transmission of Telegraphic and Telephonic Signals.
GB190117711

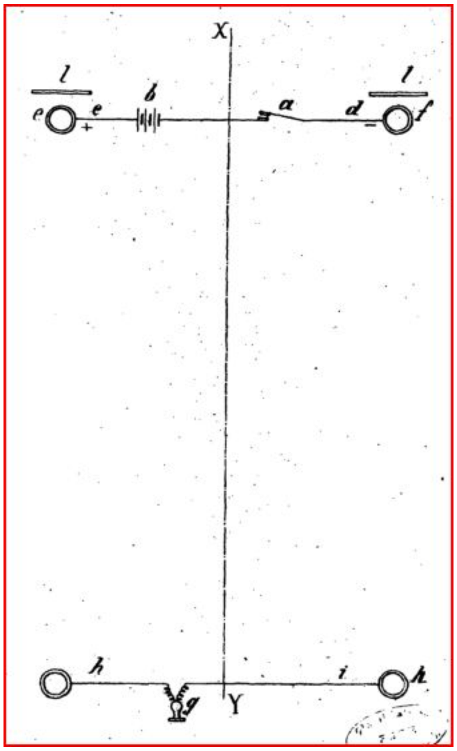
1901-02-19

The local circuits at each station are doubly earthed at e, f, j, k symmetrically about a straight line joining the stations. The earths may be formed of porous pots containing water in which the ends of the conductors are immersed, or deep ditches filled with gas coke may be employed. Insulating screens may be placed in deep ditches dug behind the earths.

This invention relates to an improved method of transmitting electrical telegraphic and telephonic signals from one point to another without the employment of wires connecting the two points.

In my improved system of transmission, the two poles of the transmitting station are put to earth and the two conductors, upon which the receiving apparatus is mounted are also both put to earth; the signals emitted by the transmitting apparatus are transmitted to the receiving station through the earth alone.

In order that my invention may be readily and clearly understood, I have represented in the accompanying drawing, by way of example only, a diagrammatic view of my device as a whole.



As shewn in the drawing, the transmitting station comprises a transmitter a one of the terminals of which is electrically connected to one of the poles of a source of electricity b whilst the other pole communicates with the earth; the second pole of the source of electricity is also run to earth and with this object the two conductors c d terminate in two porous pots e f embedded in the ground and filled with water.

The receiving station comprises a receiver 9 such as a telephone for example, the conductors h i which are put to earth by the intermediary of two porous pots j k similar to those of the transmitting station.

The porous pots of the receiving station should be arranged upon a line parallel with that which joins the two porous pots of the transmitting station, and they should be equidistant from an axis passing through the middle point of this line and at right angles to said axis.

The porous pots may advantageously be replaced by deep ditches sunk down to the humid earth, filled with gas coal or coke and containing at their centre a plate of carbon which is a good conductor, to which the transmission and receiving wires respectively are attached.

When contact is established by manipulation the transmitter a, the electric circuit passing through the source of electricity b, the conductor c, the porous pot e earth-connected to the other porous pot f the conductor d and the transmitter a, is closed. The current thus produced causes a change of condition in the ground ; all around the porous pots electric radiation is produced, the polarity of which is that of the corresponding conductor; its density decreases in proportion as it is further removed from the point of departure. This radiation is infinite with respect to space if nothing obstructs its passage.

The radiation extends so much the further according as the distance between the two porous pots of the transmitting station is greater.

These radiations, starting respectively from the porous pots e f thus create two zones one of which is positive and the other negative, the intersection of which constitutes % line absolutely neutral. It follows from this that the porous pots of the receiving station should be arranged upon either side of the neutral axis, because if these two earth connections were upon the same side they would both collect fluid of the same polarity, and in these conditions the receiver would not be traversed by any current.

In order to collect the maximum of current at the receiving station, the two porous receiving pots should be as nearly as possible equidistant from the neutral axis, as if one of the two porous pots is nearer than the other, the difference of separation of that which is the furthest removed is not only lost but is prejudical since it causes useless resistance without adding anything to the effect.

Experience has demonstrated that the disposition which furnishes the maximum of reception is that which consists in arranging the porous pots of the receiver at the same interval as separates the porous pots of the transmitting station.

In order to install my method of electrical transmission, it is first of all necessary to draw a straight line a y connecting the two stations and .then to produce upon each of these stations a line proceeding from this line x y at right angles, the said perpendicular lines being of equal length.

The transmitting and receiving appliances may be arranged at any convenient point on the conductor which connects the porous pots.

In order that the whole of the radiation emitted may be utilised at the receiving station, the propagation of this radiation is prevented (at the transmitting station upon the side opposite to that on which the receiving station is situated by burying in the ground an insulating screen l which may be of glass, tarred fabric, ebonite or the like, or by sinking a sufficiently deep ditch with or without an insulating screen.

Each time contact is made at the transmitter a, a sharp blow is audible at 'the receiving telephone g ; a second blow is heard when the circuit is broken.

It is obvious that there may be arranged both at the transmitting and receiving station transmitting and receiving appliances of the greatest possible sensibility, either for serving as relays for telegraphic purposes, or for directly receiving and recording the signals; for example an ink siphon mounted upon a galvanometric frame, or any other suitable device.

My method of transmission also permits of the transmission of speech; it is only necessary to replace the transmitter by an ordinary microphone interposed either directly upon the circuit, or arranged upon the primary of an induction coil, the secondary wire of which terminates at each extremity of the two porous pots.

It will of course be understood that in practice each station comprises both a transmitter and a receiver.

Improvements relating to the Transmission of Electric Currents
GB190108906

1901-04-30

Telegraph and telephone systems are arranged with the line-wire a connected to the center point of a battery c, c, the opposite poles of which are earthed and shunted by a normally closed circuit key g or microphone. The earth connections are made through non-polarizable cells f, f, containing, for example, two plates of copper immersed in copper-sulphate solution. The receiver is bridged between one earth and a switch h by which the transmitter is normally connected to line. The microphone may be inserted in the primary of an induction coil, the two secondaries of which oppose and are connected to the two earths and line. The two earth connections may be brought nearer together by the receiver and switch in the primary of the induction coil, so that this coil acts both to receive and transmit according to the position of the switch h. The microphone is arranged in the primary of a second induction coil.

This invention relates to improvements in the transmission of electric currents and is more particularly adapted for telegraph and telephone lines, whereby condensation in the cable is avoided, while at the same time "tapping" of the , line at any point thereof, for the purpose of ascertaining the purport of the message in transmission is rendered impossible.

My improved system of transmission comprises a single line wire between the two stations and branched at these two stations to the zero point of a circuit, the two extremities of which are connected to earth or the sea ; the current furnished at each station by a local source of electricity being sent through the circuit by means of any convenient transmitting apparatus, (such as a Morse key, microphone or the like) either direct or by induction.

Each station is furnished amongst other apparatus, with a receiving apparatus consisting of a key-instrument connected with the line-wire and permitting the current sent into the line from the transmitting station, to pass into a conductor leading direct to one of the wires running to earth and to which is connected the receiver proper.

In order to avoid the polarization of the earth-wires, each such wire is connected with a conductor leading to a copper or other metallic blade immersed in an impolarizable saline solution in which is disposed a second similar blade connected to earth or sea.

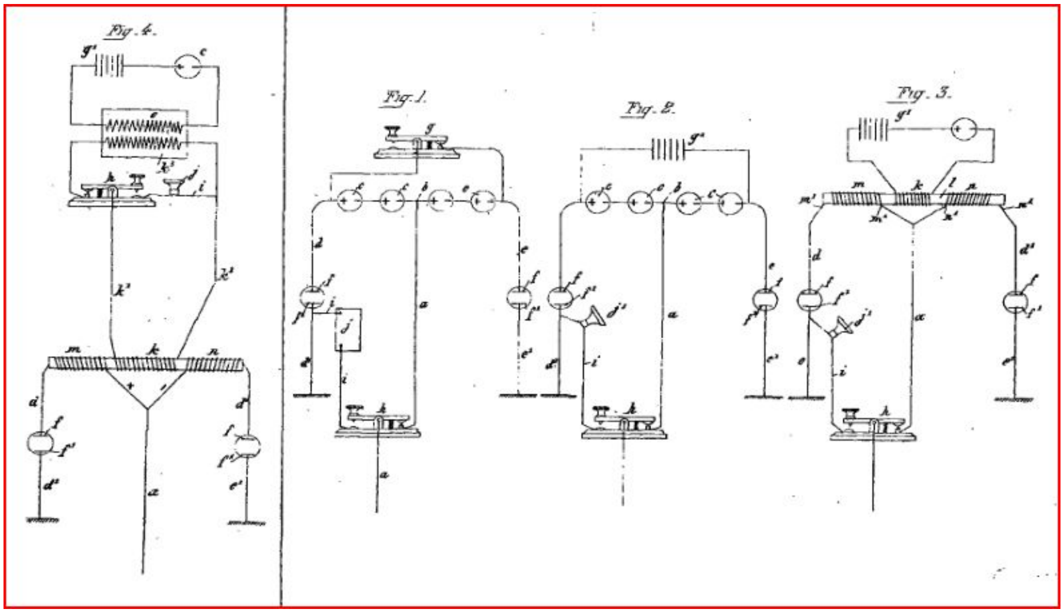
In the accompanying drawings :

Figure 1, is a diagram showing my improved system as applied to telegraphy

Figure 2, is a diagram showing the same applied to telephony.

Figure 3 shows the system of Figure 2 with induced current.'

Figure 4, shows a modified arrangement.



In all the figures the same letters of reference designate the same parts.

Referring to Figure 1 the two stations are connected by a single line-wire a, branched at the zero point b of the battery formed of the different elements c of which the end poles are connected to earth, or to sea, by a conductor d e lead- ing to a copper or other metallic plate f immersed in a liquid of good conductivity, such as for example a solution of a sulphate of copper, in which another copper plate f1 is placed connected to earth, or sea by a conductor d1 .

A transmitting apparatus g of any convenient construction, such as a Morse- key instrument, is connected with the two end poles of the battery in such a manner that in its position of rest it closes the circuit of the latter by establishing a short circuit so that no current passes, (or at most a very weak one) through the wire line a or through the earth-wires.

To send a current to the receiving station, the key 9 is depressed whereupon the short circuit is interrupted and the current is caused to pass simultaneously through the line-wire a and the earth-wires d d1 e e*. The line-wire is in reality traversed by two currents in opposite directions, so that it is in an apparently neutral state, and thus no interception of the messages can be effected for the, reason that if a receiver be interpolated, at any point of. the line, said receiver would receive two currents in opposite directions' which would neutralize each other.

Each station is furnished also with a receiving apparatus consisting of a commutator h connected with the line-wire a and permitting, when depressed, the current from the transmitter to pass into a wire i leading direct to one of the earth-wires (d1 for example) and in which is interpolated the receiving instrument j.

To receive signals sent from the transmitting station, it 'is necessary that the commutator lever h be kept depressed, so as to cause the current from the transmitting station to pass into the wire In connection with the receiving instrument.

'The connections may also be established in such a manner that when the commutator h is in its normal .position, it cuts the wire (and connects the wire with that part of the said wire which leads to the other station ; in this case for transmitting a signal it is necessary to depress the commutator lever h previously so as to re-establish the continuity of the line-wire and the operator then acts on the key-lever g as hereinbefore stated.

My arrangement is equally applicable to telephonic messages as will now be explained with reference to Figure 2, The transmitting instrument g is in this case replaced by a microphone g1 and the receiving instrument j is replaced by a telephone receiver j 1 the operation of the arrangement is exactly, the same as that above described.

The vibrations of the microphone cut the short circuit and the current from the local, source of electricity thereupon passes over the line-wire a and the earth-wires d d1 c el as previously stated.

The telephonic message is received in the same manner as before through the intervention of the commutator h which passes the current, sent from the transmitting station; to the telephonic receiving instrument jl.

The line-wire may also be operated by induction currents a3 is indicated at Figure 3.

The local circuit in which the transmitting apparatus (for instance, the microphone g1) is inserted comprises a primary winding k surrounding a central soft-iron core, or bundle of wires, l which is further provided with two secondary windings m m in opposite directions. The line wire a is connected to each of these secondary windings at the two extremities m1 n1 of opposite polarity and the opposite extremities ms p2 are connected with the earth-wires d d c set in the manner already explained.

When operating the transmitting apparatus or when speaking into the microphone 0 for example, induction currents are generated in the secondary windings m n and they then affect the receiving apparatus jl at the receiving station as already stated.

The primary winding and the two secondary windings may have the three wires wound in the same direction upon the soft iron core and the two extremities of the primary convolutions are connected with the local circuit in which is interpolated the transmitter while two extremities of opposite polarities of the secondary convolutions are connected to line and the two osiers to earth as previously explained.

In my improved transmitting arrangement the two earth wires at 'each station must be the more separated from each other the longer the distance is between the two stations so that the resistance of the earth between the said earth-wires will be sufficient to cause the single line-wire to be traversed by the greatest possible quantity of the current.

In order to reduce as far as possible the distance between the earth-wires the beginning of the single wire a and the wires rl rl' leading to earth are advantageously rm distance from the transmitting instrument and receiving instrument respectively at the telegraphic or telephonic station and thus permit the two earth connections of the two telegraphic or telephonic stations to be placed nearer each other.

The telegraphic or telephonic station is then divided and the transmitting instrument is connected with the magnet with its earth connections and line wire a ' by two conducting wires kl k2 connected with the ends of the convolutions k which generates induction currents in the secondary windings m n (Figure 4).

The current sent into the conducting wires k1 k2 and. passing through the convolutions k may itself be an induced current generated in the coil k3 when a current from the source of electricity c is passing through the. primary coil o through the action of the transmitting microphone gl for example.

In the case when' the distance of the telegraphic or .telephonic transmitting station from its earth-connections is not too excessive the current traversing the conductors k1 1.:2 instead of being an induction current may be furnished direct by the source of electricity of such station, and naturally the, transmitting instrument, (microphone or 'key), and the source of electricity are then placed direct in the circuit;1 k2.

An interrupter A interpositioned in the conductor kl permits of cutting the circuit in leading to the secondary coil k3 and of closing the circuit for the conductor i leading to the conductor k 2 in which is interpolated' the receiving instrument j.

Thus the coil k is either inductor or induction according to whether there is transmission or reception.

It is to be well understood that my system of transmission is entirely independent of the nature of the telegraphic or telephonic apparatus employed therewith, and that the source of electricity at the stations may be of any convenient kind, either derived from a battery, accumulators, dynamo, magneto-electric machine or the like.

COMPLETE SPECIFICATION.

This invention elates to improvements in the transmission of electric currents and is more particularly adapted for telegraph and telephone lines, whereby condensation in the cable is avoided, while at the same time "tapping" of the line at any, point thereof, for the purpose of ascertaining the purpose of the message in transmission is rendered impossible.

My improved system of transmission comprises a single line-wire between the two stations and branched at these two stations to the zero point of a circuit, the two extremities of which are connected to earth or the set; the current furnished at each station by a local source of electricity being sent through the circuit by means of any convenient transmitting apparatus, '(such as a Morse key .microphone or the like) either direct or by induction.

Each station is furnished, amongst other apparatus, with a receiving apparatus consisting of a key-instrument connected, with the line-wire and permitting the current sent into the line from the transmitting station, to pass into a conductor leading direct to one of the wires running to earth and to which is connected the receiver proper.

In order to avoid the polarization of the earth-wires, each such wire is connected with a conductor leading to a copper or other metallic blade immersed in an impolarizable saline solution in which is disposed a second similar blade connected to earth or sea..

In order that my invention may be clearly understood and readily carried into effect I will now proceed to describe the same more fully with reference to the drawings accompanying my Provisional Specification in which:.

Figure 1, is a diagram showing my improved system as applied to telegraphy.

Figure 2, is a diagram showing the same applied to telephony.

Figure 3 shows the system of Figure 2 with induced current.

Figure 4 shows a modified arrangement.

In all the figures the same letters of reference designate the same parts.

Referring to Figure 1 the two stations are connected by a single line-wire a branched at the zero point b of the battery formed of the different elements c of 'which 'the end poles are connected to earth, or to sea, by a conductor d e leading to a copper or other metallic plate f immersed in a liquid of good conductivity, such as for example a solution of sulphate of copper, in which another copper plate f1 is placed connected to earth, or sea by a. conductor d1 e1.

A transmitting apparatus q of any convenient construction, such as a Morse-key instrument, is connected with the two end poles of the battery in such a manner that in its position of rest it closes the circuit of the latter by establishing a short circuit so that no current passes, (or at most a very weak one) through the wire line a or through the earth-wires.

To send a current to the receiving station, the key g is depressed whereupon the short circuit is interrupted and the current is caused to pass simultaneously through the line-wire a and the earth-wires d d1 e el. The line wire is in reality traversed by two currents in opposite directions, so that it is in an apparently neutral state, and thus non interception of the messages can be effected for the reason that if a receiver be .interpolated at any point of the line, said receiver would receive two currents in opposite directions which would neutralize each other

Each station is furnished also with a receiving apparatus consisting of a commutator h connected with the line-wire a and permitting, when depressed. the current from the transmitter to pass into a wire i leading direct to one of the earth-wires (d1 for example) and in which is interpolated the receiving instrument j.

To receive signals sent from the transmitting station, it is necessary that the commutator lever h be kept depressed, so as to cause the current from the transmitting station to pass into the wire i in connection with the receiving instrument.

The connections may also be established in such a manner that when the commutator h is in its normal position, it cuts the wire' a and connects the wire i with that part of the said wire which leads to the other station; in this case for transmitting a signal it is necessary to depress the commutator lever h previously so as to re-establish the continuity of the line-wire and the operator then acts on the key-lever as hereinbefore stated.

My arrangement is equally applicable to telephonic messages as will now be explained with reference to Figure 2. The transmitting instrument g is in this case replaced by a microphone 1 and the receiving instrument j is replaced by a telephone receiver il the operation of the arrangement is exactly the same as that above described.

The vibrations of the microphone cut the short circuit and the current from the local source of electricity thereupon passes over the line-wire a and the earth-wires d d1e e1 as previously stated,

The telephonic message is received in the same manner as before through the intervention of the commutator h which passes the current sent from, the transmitting station to the telephonic receiving instrument j1.

The line wire may also be operated by induction currents as is indicated at Figure 3.

The local circuit in which the transmitting apparatus (for instance, the microphone g1). is inserted comprises a ,primary winding k surrounding a central soft iron core,, or bundle of wires, 1 which is further provided with two secondary windings m n in opposite directions. The line wire a is connected to each of these secondary windings at the two extremities in n1 of opposite polarity and the opposite extremities m2 n2 are connected with the earth wires clt c ex in the manner already explained.

When operating the transmitting apparatus or when speaking into the microphone for example, induction currents are generated in the secondary windings m n and they then affect the receiving apparatus l at the receiving station as already stated. The primary winding and the two secondary windings may have the three wires wound in the same direction upon the soft iron core and the two extremities of the primary convolutions are connected with the local circuit in which is interpolated the transmitter while two extremities of opposite polarities of the secondary convolutions are connected to line and the two others to earth as previously explained.

In my improved transmitting, arrangement the. two earth wires at each. station must be the more separated from each other the longer the distance is between the two stations so that the resistance of the earth between the said earth-wires will be sufficient to cause the single line-wire to be traversed by the greatest possible quantity of the current.

In order to reduce as far as possible the distance between the earth-wires the beginning of the single line wire a and the wires d d1 leading to earth are advantageously removed at a distance front the transmitting instrument and receiving instrument respectively at the telegraphic or telephonic station and thus permit the two earth connections of the two telegraphic or telephonic stations to be placed nearer each other.

The telegraphic or telephonic station is then divided and the transmitting instrument is connected with the magnet with its earth connections and line wire z by two conducting wires k' k2 connected with the ends of the convolutions which generates Induction currents in the secondary windings m n (Figure 4).

The current sent into the conducting wires k1 k2 .and, passing through the convolutions k may itself be an induced current generated in the coil k3 when a current from the source of electricity c is passing through the primary coil or through the action of the transmitting microphone f/I for example.

In the case when the distance of the telegraphic or telephonic transmitting station from its earth connections is not too excessive the current traversing the conductors k le2 instead of. being an induction current may be furnished direct by the) source, of electricity of such station, and naturally transmitting instrument (microphone or key) and the source of electricity are then placed direct in the circuit leI k-S.

An interrupter It interpolated in the conductor k1 permits of cutting the circuit in leading to the secondary coil k3 and of closing the circuit for in conductor i leading to the conductor 3 in which is interpolated the receiving instrument j1.

Thus the coil k is either inductor or induction according to whether there is transmission or reception.

It is to be well understood that my system of transmission is entirely independent of the nature of the telegraphic or telephonic apparatus employed therewith, and that the source of electricity at the stations may be of any convenient kind,

---

Improvements in Connections of Telephonic and Telegraphic Instruments to Conducting Lines.
GB189706773

1897-03-15

Telegraph and telephone lines are arranged so that any pair of lines bearing instruments may be used as a lead or return for another set of instruments without interference. Thus, as an example, four metallic circuits carry four separate sets of instruments individually but may have circuits A and B, C and D, used as other metallic circuits, or A and B may form a lead and C and D a return for a seventh metallic circuit. The Specification describes telephone instruments as used on the metallic circuits and telegraph or telephone instruments inserted in the earth return circuits. Fig. 1 shows a pair of lines L<1>, L<2> forming a metallic circuit and capable of use as the line with an earth return through L<3>, L<3>, the lines L<2> being connected to the loop at the centre of the secondary coil S', S<2> of the induction coil X. The receiving-instrument is shown in a bridge, such as Z. The positions of the transmitting T and receiving R instruments may be reversed. Each side of a metal loop may also be used as the line with an earth return.

This invention relates to the connecting of telephonic and telegraphic instruments to conducting lines in such a manner that several telephonic and telegraphic messages can be simultaneously transmitted without interfering with one another.

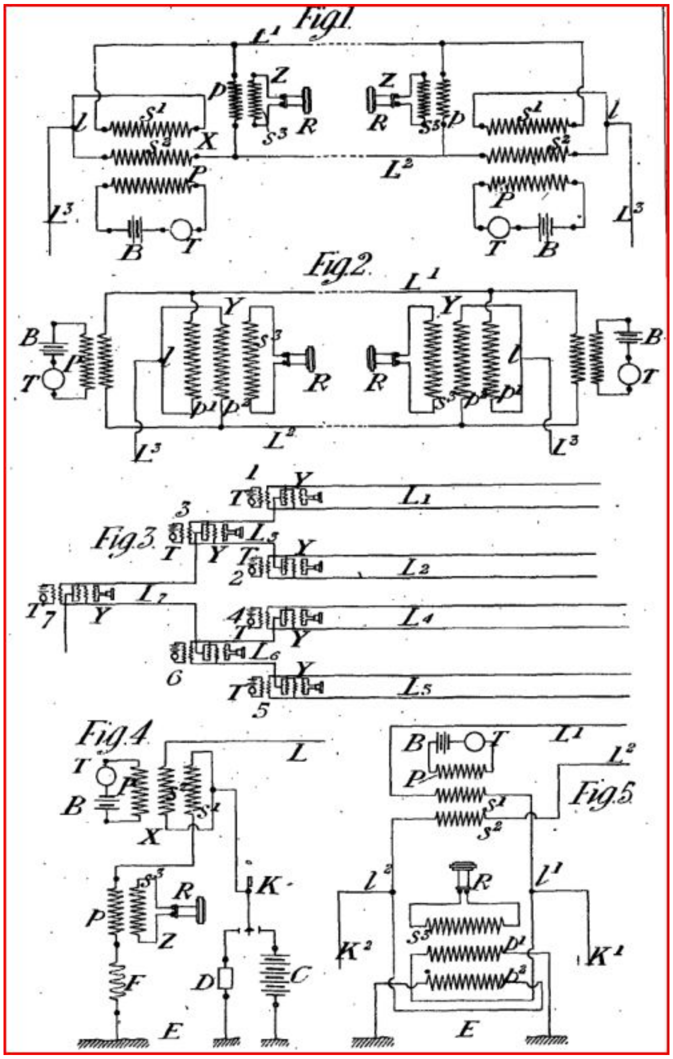
Fig. 1 of the accompanying drawings shews diagrammatically connections for a telephone and also for another telephone or telegraph to a double conducting line.

Fig. 2 shews a modification.

Fig. 3 shews how seven sets of the connections may be applied to four double conducting lines.

Fig. 4 shews the connections for a telephone and telegraph to a single line with earth return.

Fig..5 shews connections for telephoning over two telegraph lines one of them forming a metal return.



Referring first to Fig. 1 the two lines Ll L2 are at each end connected as shewn at X through two equal secondary coils 8 1 and s 2 wound with a primary coil P which is in circuit with a telephone transmitter T and local battery B.

The lines L1 L2 are so connected to the secondary coils 8 1 s 2 that the currents induced in the lines by the telephone transmitter are always in opposite directions.

The telephone receiver R, as shewn at Z, is in circuit with a secondary coil 8 3 wound with a primary coil p connecting the two lines L1 L2.

At a point l intermediate to the coils s1 s2 a third line L3 is connected, this line being employed for telephone or telegraph transmission. When either of the telephone transmitters T is employed, the induced currents pass through the primary coil p thus causing the receivers R to act. But should any current flow by L3 it must flow in opposite directions through 8 1 and s2, and therefore in the same direction along the lines L1 L2 so that it cannot influence the receivers R nor the transmitters T. At each end a line L3 may be connected as shewn by Y, Fig. 2, at l a point intermediate to two equal primary coils p1 p2 which connect the lines Ll LO and are wound with the secondary S3 of each telephone receiver R.

With connections thus arranged any current flowing in the same direction through the coils pl p 2 actuates the telephone receivers R, whereas a current from L3 flows in opposite directions through the coils pl p 2 and therefore is ineffective on the receivers R. By combining several ordinary transmitters T and several of the receiver arrangements marked Y in Fig. 2 with a number of double lines as shewn in Fig. 3, a number of messages can be sent over these lines without interfering with each other.

Thus referring to Fig. 3 the transmitter 1 works over the pair of lines L1 in the - usual way, one of these lines serving as metal return. In like manner the transmitter 2 works over the pair L2, transmitter 4 over the pair L 4 and transmitter 5 over the pair L 5. Again the transmitter 3 works through the pair of lines L 3 and the two pairs L 1 and L 2, one of these pairs serving as metal return.

In like manner the transmitter 6 works through the pair of lines L 6 and through the two pairs L 4 L 5. Finally the transmitter 7 works through the pairs of lines L 7 and through the two pairs L 3 and L 6 and the. four pairs L 1 L 2 L 4 and L 5, two of these pairs such as L 4 and L 5 serving as metal return.

Obviously this system may be duplicated, and reduplicated so that one transmitter can be made to work over 8 pairs or 16 pairs of lines or other multiple of 4.

As shewn in Fig. 4 a telephone and a telegraph are connected to one line L having earth return. In this case X and Z are the telephone arrangements so marked in Fig. 1, K is the key, C the battery and D the receiver for telegraphing in the connection of Z to earth there is an adjustable resistance F to balance that of the line. As shewn in Fig. 5 two sets of the telegraphic connections shewn in Fig. 4 and two lines Ll L2 which may be both to one place or each to a different place with earth return are combined with one telephone arrangement.

The transmitter T by its primary P induces currents in the secondaries $ 1 89 both in the same direction and therefore in opposite directions in the lines Ll L2. The currents being in the same direction in p1 and p2 act on the secondaries 1 3 of the receivers 1,. Currents from the telegraph gi dividing at 11 pass in opposite directions through sl and pl and therefore do not affect the telephonic receivers. And in like manner the currents from the telegraph K2 are ineffective on the receivers.

For the sake of clearness the primary and secondary coils have been shewn in the form of many lines side by side.

It is to be understood however that they are wound in each case all on one bobbin.

In Figs. 3,4 and 5 the arrangements are shewn at only one end of the conducting lines.

It is to be understood however that they are symmetrically repeated at the other end as shewn in Figs. 1 and 2.

COMPLETE SPECIFICATION.

This invention relates to the connecting of telephonic and telegraphic instruments to conducting lines in such a manner that several telephonic and telegraphic messages can be simultaneously transmitted without interfering with one other.

Figure 1 of the drawings accompanying my Provisional Specification shews diagrammatically connections for a telephone and also for another telephone or .telegraph to a double conducting line. Figure 2 shews a modification. Figure 3 shews how seven sets of the connections may be applied to four double conducting . lines: Figure 4 shews the connections for a telephone and telegraph to a single line with earth return. Figure 5 shews connections for telephoning over two telegraph lines one of them forming a metal return.

1 . Referring first to Figure 1 the two lines Ll L2 are at each end connected as shewn at X through two equal secondary coils s1 and 8 2 wound with a primary coil P which is in circuit with a telephone transmitter T and local battery B.

The lines Ll L 2 are so connected to the secondary coils 8 1 s'" that the currents induced in the lines by the telephone transmitter arc always in opposite directions.

The telephone receiver R, as shewn at Z, is in circuit with a secondary coil s3 wound with a primary coil p of high resistance connecting the two lines L1 L2.

At the point intermediate to the coils sr s 2 a third line L3 is connected, this line being employed for telephone or telegraph transmission. 'When either of tho telephone transmitters T is employed, the induced currents pass through tho primary coil p thus causing the receivers R to act. But should any current flow by L3 it must flow in opposite directions through sl and s2, and therefore in the same direction along the lines Ll L2 so that it cannot influence the receivers It nor the transmitters T. At each end a line L3 may be, connected as shewn by Y, Figure 2, at l a point intermediate to two equal primary coils p1 p2 which connect the lines L1 L2 and are wound with the secondary 8 3 of each telephone receiver R. With connections thus arranged any current flowing in the same direction through the coils yx actuates the telephone receivers R, whereas a current from L3 flows in opposite directions through the coils p1 p2 and therefore is ineffective on the receivers R. By combining several ordinary transmitters T and several of the receiver arrangements marked Y in Figure 2 with a number of double lines as shewn in Figure 3, a number of messages can be sent over these lines without interfering with each other.

Thus referring to Figure 3 the transmitter 1 works over the pair of lines L 1 in the usual way, one of these lines serving as metal return.. In like manner tho transmitter 2 works over the pair L 2, transmitter 4 over the pair L 4 and transmitter 5 over the pair L 5. Again the transmitter 3 works through the pair of lines L 3 and the two pairs L 1 and L 2, one of these pairs serving as metal return.

In like manner the transmitter ti works through the pair of lines JLA b and through the two pairs L 4 L 5. Finally the transmitter 7 works through the pairs of lines L 7 and through the two pairs L 3 and L 6 and the four pairs L 1 L 2 L 4 and L 5, two of these pairs such as L 4 and L 5 serving as metal return.

Obviously this system may be duplicated, and reduplicated so that) one transmitter can be made to work over 8 pairs or 16 pairs of lines or other multiple of 4.

As shewn in Figure 4 a telephone and a telegraph are connected to one line L having earth return. In this case X and Z are the telephone arrangements so marked in Figure 1, K is the key, C the battery and D the receiver for telegraphing.

In the connection of p to earth there is an adjustable resistance F to balance that of the line. As shewn in Figure 5 two sets of the telegraphic connections shewn in Figure 4 and two lines Ll L2 which may be both to one place or each to a different place with earth return are combined with one telephone arrangement.

The transmitter T by its primary P induces currents in the secondaries sl S2 both in the same direction and therefore in opposite directions in the lines L1 L2. The currents being in the same direction in pI and pS act on the secondaries i1 of the receivers It.

Currents from the telegraph K1 dividing at 1 1 pass in opposite directions through sl and I > I and therefore do not affect the telephonic receivers. And in like manner the currents from the telegraph K2 are ineffective on the receivers.

The connections of p1 and p2 to earth may have suitable resistances as shewn at F in Figure 4.

For the sake of clearness the primary and secondary coils have been shewn in the form of many lines side by side.

It is to be understood however that they are wound in each case all on one bobbin.

In Figures 3,4 and 5 the arrangements are shewn at only one end of the conducting lines.

It is to be understood however that they are symmetrically repeated at the other end as shewn in Figures 1 and 2.,

---

Perfectionnements aux bobines d'induction
FR382386

1908-02-05

The present invention relates to an improved induction coil in order to obtain induction currents in very short periods. These currents, whose durations are extremely short 5, enjoy special properties which find application mainly in telegraphy and wireless telephony.

This induction coil is characterized by the absence of the magnetic core and the winding mode of the inductor and the armature on a short length coil, but a very large diameter, the inductor coil being virtually drowned in May 1 the armature winding.

The appended drawing schematic represents for example an induction coil according to the present invention.

FIG. 1 is a section along line A-20B of FIG. 2 ;

FIG. 2 is a plan.

Fig.1

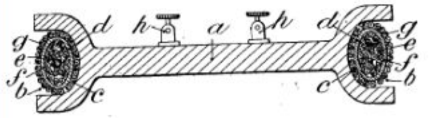


Fig.2

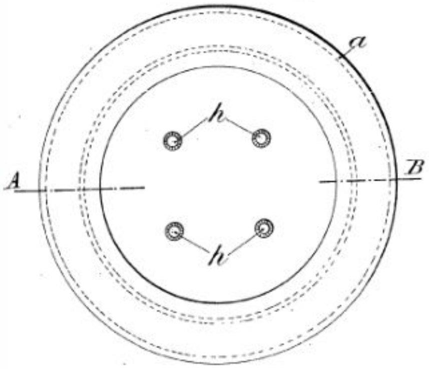


As shown in these drawings, this coil has a very large diameter which can be up to several meters; 26 is drawing the round, but it could equally be square or affect any other polygonal shape. This reel is very long because all winding son are housed on its outskirts in a suitable groove b; it will be understood by 3o begins winding on the rim of this kind of pulley a first layer of wire induced E and then covered with a suitable insulating and d are wound over this insulating layer the inductor wire E which is covered another 35 isolated layer; we **réuuïi uêUi** the insulating layers d and f, so as to isolate the inductors e and ends the coil by an external winding armature wire g. ko

Is carried out in this way a large-diameter ring compound induced son c, g, containing a central core of an adequately insulated son inductors.

The machine has four terminals 5 h which two are used to secure the ends of the armature winding and the other two ends of the inductor winding.

We can arrange several induced son and son more inductors; in this case, each terminal 5o h will be replaced by a multiple switch that will bring together the different armatures on, and the different inductors on, either voltage or the contrary in quantity, following the effects that one wishes to obtain.

Dispositif de transmission téléphonique
FR377785

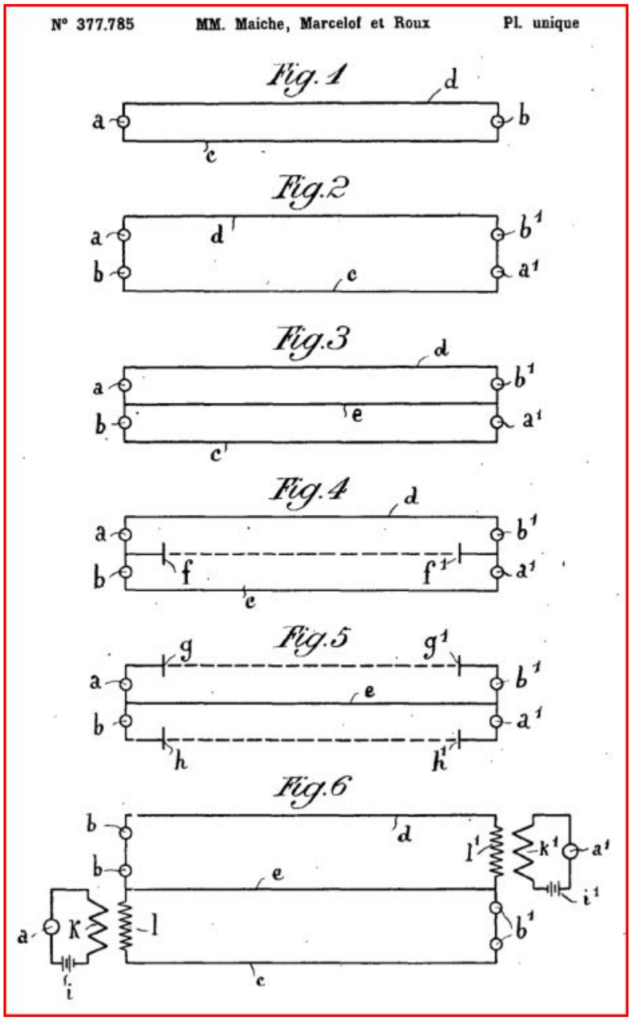
1907-09-14

Telephone transmission system of mounting each station transmitter and or serial receivers and to bring the two stations by three son line, including 5o first two respectively together the poles of the two stations and the third is mounted derivation at a point of each station caught between the transmitters and the receiver or receivers, one or even two of these three son may be replaced by equivalent landings.

The present invention provides a way to increase the distance at which it is possible to call or to increase the intensity of sound transmitted at a given distance 5.

When installing a regular telephone line, it is customary to bring the two stations using two wires, one for the second round for the return; at-10 there is no fear induction from neighboring lines, one connecting the two stations by a thread alone and return through the ground at each station.

FIG. 1 of the accompanying drawing shows the 15 most simple provision of a regular line with two son; there is one at each station magnetic phone, a1 met by both son line c and d; when speaking in the phone, the phone is 30 a1 receiver and vice versa; this provision is entirely satisfactory from the standpoint of the actual transmission, but it has the obvious disadvantage that the two parties can not break interfere, each necessarily listen to while the other speaks .



To overcome this disadvantage, it immediately offered to have each transmitter station a phone or a 1 and a receiver or telephone b bl, allowing 3 to the two interlocutors to talk while listening. This solution suffers a disadvantage from the standpoint of the transmission; in fact, as shown in Fig. 2, the four phone a, b, a}, bx 3 are mounted in series on the line cd, so that the sound transmitted by a transmitter has or a1 necessarily travels in addition interesting b1 or b receptor both other phones of the circuit. The telephone circuit thus unnecessarily h has a high resistance which reacts disadvantageously either on the possible length of the line cd, either the intensity of the sound transmitted to a given line length.

The present invention relates to a device easy positive h to remedy the drawbacks both of the two transmission systems according to Fig. 1 and 2 and make a new telephone transmission system providing both the benefits of the 5 two known systems.

As shown in Fig. 3, this invention is simply to dispose between the two stations a third e line wire terminating at each station between the telephone transmitter 5 tor a or a1 and the receiver phone b or b1. In these conditions the wall sent by "will be fully received by b1 without crossing unnecessarily b and a1 resistance and vice versa speech transmitted by a1 will be fully received by b.

The need for three son line c, d, e 5 is required when the line is around other transmissions; but when isolated, it can simplify the transmission as shown in Fig. k or 5.

According to FIG. h, the wire line drifted o-tion e is deleted and replaced by a ground f and f1 taken at each station between the transmitter and receiver.

In special cases, it is even possible to reduce the line to a single wire e in '5 with each station two landings g, h and # 1, h1), the receiver and transmitter are each disposed station in series between the two landings; under these conditions, the two conductors c and d are formed by o the ground and there is no longer a single line wire e.

In the above, to simplify the description and drawings, we assumed the exclusive use of magnetic phones; 5 Fig. 6 shows the circuit diagram in the case of induction phones. In this case each position i includes a battery, a transmitter microphone and primary k of an induction coil, mounted in series o on a closed circuit; the line circuit c, d comprises series headphones b, b and b1, b1 and side and ll of the coil. In this

If the invention is to attach the derivative e line wire between the two receivers b, b or i1, A1 on the one hand and the secondary or ll 35 on the other hand, as shown in FIG. 6.

The result of these provisions is summed up by the possibility of quadrupling of the intensity of the reception for a given length of line, or the length of the line Zio maintaining the same intensity.

Nouveau mode de transmission sans fils des courants télégraphiques et téléphoniques en employant comme conducteurs la terre et l'eau
FR320267

1902-12-05

To understand our invention, it is good to remember that in an ordinary telegraph line a thread, more or less isolated, from a point to another, communicates with earth at each end. A power source; and a transmitter unit are sandwiched between the starting line and earth. Upon arrival, a receiver also communicates with the line and the earth.

We know that each of the posts supporting the line passes a small amount of power that is lost in the ground. Large amount of current is now lost all **plus 1 large 5** that the distance between stations is itself larger and, consequently, the number of' poles is higher. Loss can become considerable, without preventing transmissions. It may even happen that the ao thread without being broken, drags on earth there for a certain length of son'parcours and continues to allow the current of a shift to another, albeit very weakly,

The experience proved us uninsulated conductor could even, for certain distances, be simply placed on the ground and that transmissions would nevertheless be possible.

We are able to continue, transmit signals is greatly increased if, at each end, the uninsulated wire touching the ground, met in a well-insulated wire that extends the line to a ground to the point where so are transmitters and receivers.

It is understood that the ground at the end of a secluded part forces the return current from sinking into the depths of the earth ho and that, consequently, there is an infinitely small closure point where the uninsulated wire touches the ground. In other words, the loss suffered in ground contact, the uninsulated wire, is even less than each end of uninsulated wire so is an insulated wire from the ground at a greater distance.

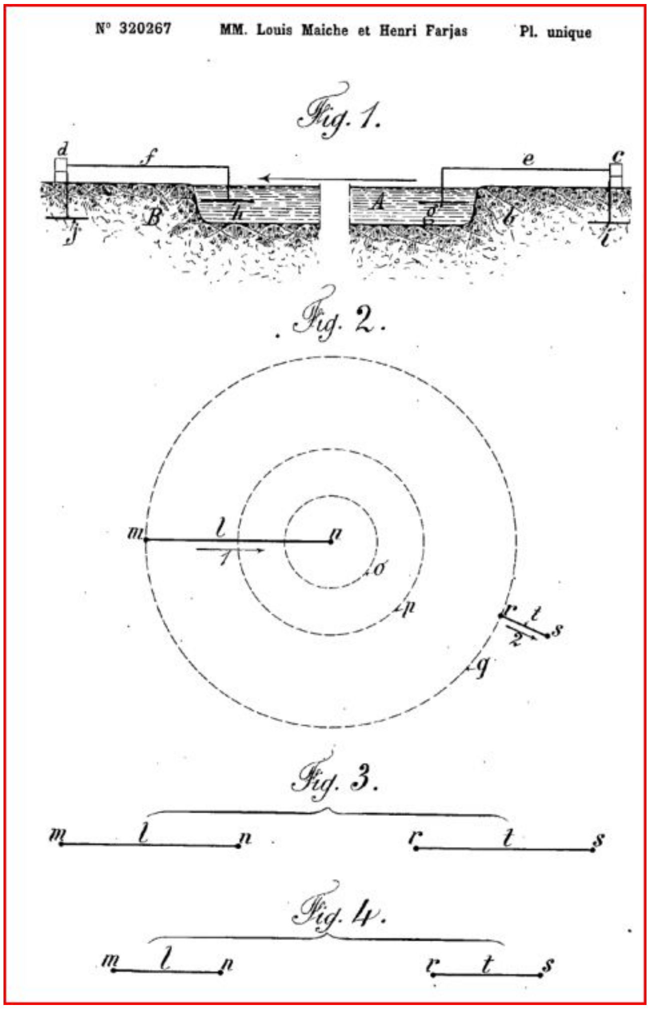
Hence, if the lead wire, instead of iron, consisting of a much less conductive material, coal, for example, everything would be the same way. We also recognized that even when iron, coal or other similar material, are replaced by placed water, salt if possible, and, consequently, by a stretch of sea or any other part of sea whose geographic provision lends itself to this kind of installation.

When it comes to cross an arm of the sea, the isolated line extension is placed preferably in the direction of the straight line through the two points to be connected.

In case one transmission on a role, isolated leagues will be perpendicular to the straight line joining the two stations.

Isolated lines will not be too long, and therefore, will provide not only coast to coast, but between two points inland. The thickness of the salt water layer being at even greater depths, only about the thickness of the land mass, the proportions remain between water and adequate the earth so that water plays exactly the same role that the uninsulated conductor touching the ground.

To make our evplications as clear as possible, we have shown diagram-matically, in the accompanying drawing, an installation in which our invention is applied.



A is the sea (Fig. I) and 13 b are both shores, c and d both stations, e and f insulated, and the plates located in the water, i and it updates earth.
We see that the sea is an extension isolated son e and f, and it plays the role of an uninsulated conductor based on floor.

To make it clear how 3 o operates the propagation of electric currents, we assume an isolated line (Fig. A) within two earthed m and n. If the current is moving in the direction of the **llèche**, electricity arriving ashore in n flourishes spheres 3.) concentric o, p, q, etc., all points of each sphere simultaneously receiving the same amount of electricity if the propagation medium is uniform. Be grounded in r therefore receive the current along the earth m, r and if this land is connected by a line by t, s land to another, even very close to her, the current finding less resistance in the isolated line in the middle (Jun separates the two nets land, will follow this line, as shown in llèche a. It will be thus possible to establish a wireless communication between any point of the line / on which find transmitting devices, and any point on line T which will be **appareds** receptors.

To establish simultaneously on each of the leagues and t, a position transmitter and a receiver will require that the line is the same length as the line 1, J J as shown in Fig. 3.

If the medium is found to be twice as conductor between h and r between m and n, on the one hand, and between r and s on the other hand, the lines l and t may have as half the length of the distance between the points n and r (fig.û).

Of course, transmissions based on the principle that we have indicated, may be made by taking as con- bo different producers, not only the earth and the sea water, but the earth and air, land in this case, acting as a better conductor brought by the air; the insulated wire from the earth lead to the air at each station 7. tion to a more or less remote distance according to the distance that would take. It is obvious that the latter provision, the sea and fresh water advantageously replace the earth. 7°

In summary, we claim as our exclusive property, the new method, described above, transmission without telegraph and telephone currents, said transmission mode of making pass in a conductive medium the current emitted by the base station and to receive on arrival in this current an insulated wire of suitable length, which are sandwiched the receivers and resulting in a second medium whose specific conductivity is less than that of the first medium, but passes the total quantity of electricity because of its mass which is greater than that first medium, an insulated wire, on which the transmitting devices is also leading into the second medium, so that the first medium is an extension of two isolated lines, and the second medium acts as the return wire, the two isolated lines to be used both for shipping and for the reception.

Un nouveau mode de transmission et de réception des courants télégraphiques et téléphoniques sans autre conducteur que la terre ou l'eau

FR318007

1902-10-03

In an electrical circuit consisting of a power source and a metallic conductor whose ends are grounded, which closes the circuit, the earth acts as 5 driver not only a straight line between the two landings, but on a almost infinite extent; However, with a power density decreasing in proportion to the distance.

If parts of the ground are better conductors than others (because of the moisture, the saltiness of the water or any other cause) the current preferably passes through these parts describing curves or bends as does a river following the slopes of the terrain.

It follows that if, on part of the land used as return conductor, it artificially creates a better conductor line as the earth, it will be traversed by the current in preference to any other lower conductive part.

The effect is much more complete and can collect the current and note its existence when the best conductive line is insulated from earth and communicates with it by its ends. The current that would have crossed the land finding a wise not easier by the wire preferably follows and restores much faster electrical neutrality of the ground. It is isolated by cutting the line at any point that can be inserted in the course of the current instruments (telegraphic or telephonic receivers) that can detect its existence.

It is understood that if the isolated artificial line is a very good conductor, if its ends are connected to metal surfaces large enough in contact with the ground, the closing of the circuit will cause the ground to be in a state of electrical neutrality absolute.

Under these conditions, if a current electric is sent intermittently in the metal line, charge the earth, for each issue, a certain amount of electricity instantaneously discharge into the isolated artificial line.

Experience has shown that these phenomena can occur even when there is almost no gap between the two landings transmitter station or between two plates that collect the color rant crossing the line isolated the receiving station, to the condition that at each station the plates which lead to the two lands are carefully insulated from each other by means of a sufficiently thick insulating separation that no induction effect or condensation on one another can occur, and fairly large compared to the dimensions of the plates to prevent current from closing on itself too close to the to start. The current is so obliged to flourish "right and left of the landings, and the point where the positive and negative electric waves begin to reach is considerably related. I can further increase the desired effect by minimizing the current closure on itself through a number of insulating walls arranged below the plates to prevent **farm-i o ture** of the circuit by the depth of the earth, on the side opposite that in which the transmission must be received and, if necessary, above the plates.

In general, the plates will be placed vertically on either side of an insulating wall, their smaller dimensions being turned to the opposite position.

I can also use a wide insulating tube divided in two by a thick wall normal to isolated generators. The plates will be set back to back on either side of this partition in the interior of the tube and placed in communication with the outer conductor through insulated **son**.

The tube may be straight, or consists of two parts forming between them an angle properly calculated so that the circuit is closed by the earth is done by almost entirely in the **3 o** where the current is sent.

It is obvious that the installation is completed by transmitters and telegraph or telephone receivers that may be any, as the source of electricity.

I claim as my exclusive new property above described transmission and reception of telegraph and telephone currents without other driver as land or water, said system of separating the two landings each position by established insulating material to prevent the production of induction phenomena of condensation and the circuit closing on or by the depth of the earth, and force the air to flourish right and left, so that they can begin to get to and distant from the transmitter station, the two earthed of each position can thus without drawbacks, are moved towards one another until they fit on either side of the same insulating wall.

(57) **ABSTRACT**

An energy harvesting circuit includes one or more broadband or narrow band antennas to detect WIFI (wireless fidelity) or other RF (radio frequency) signals. The signals are rectified and voltage multiplied, and the resultant DC voltage is provided to a power management circuit. The output of the power management circuit charges a lithium battery or other storage device within the energy harvesting circuit. The energy stored in the battery or storage device is provided through a DC/DC converter circuit to a USB output connector to power or recharge the batteries of an external electronic device connected to the USB output connector of the energy harvesting circuit.

METHOD AND APPARATUS FOR HARVESTING ENERGY

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is related to U.S. Provisional Application Ser. No. 61/335,459, filed on Jan. 7, 2010, and entitled “Method and Apparatus for Harvesting Energy from WIFI Signals”, U.S. Provisional Application Ser. No. 61/402,481, filed on Aug. 31, 2010, and entitled “Method and Apparatus for Harvesting Energy”, and U.S. Provisional Application Ser. No. 61/404,290, filed on Sep. 30, 2010, and entitled “Method and Apparatus for Harvesting Energy”, the disclosures of which are incorporated herein by reference and on which by priority is hereby claimed.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to energy conservation methods and devices, and more particularly relates to devices which can harvest energy.

2. Description of the Prior Art

Many devices have been proposed or implemented which harvest energy from different types of naturally-occurring energy sources. These energy sources include solar, wind, tide, current and wave power, the energy of which is converted by such devices into electrical power to supplement or replace electrical power provided by a power company. Except for solar cells powering hand held calculators and other small electronic devices, most energy harvesting apparatus are relatively large, expensive and inefficient. To the knowledge of the inventor, there are no RF (radio frequency) commercially available devices which harvest energy from WIFI (wireless fidelity), WiMax, Satellite Radio, Cellular Phone (850 MHz to 900 MHz and 1.8 GHz-1.9 GHz), or any 2.4 GHz and UHF TV signal sources to power or recharge the batteries of small electronic devices, such as cellular phones, personal digital assistants (PDAs), MP3 players or the like.

OBJECTS AND SUMMARY OF THE INVENTION

It is an object of the present invention to provide a device which harvests energy from WIFI, WiMax, Satellite Radio, Cellular Phone (850 MHz to 900 MHz and 1.8 GHz-1.9 GHz), and any 2.4 GHz and UHF TV signals or any signal from outdoor antenna or CATV feed through any “F” type connectors at consumers’ homes.

It is another object of the present invention to provide a method and device for harvesting energy from two or more alternative sources of energy such as solar and vibration from a microphone for powering or recharging the batteries of an electronic device.

It is yet another object of the present invention to provide an energy harvesting device which stores energy for later use to power an electronic device connected thereto.

It is a further object of the present invention to provide a device for harvesting energy from both WIFI or other RF signals and solar power to power an external electronic device connected thereto.

It is yet a further object of the present invention to provide apparatus for harvesting energy from WIFI or other RF signals which converts WIFI or RF signals received thereby into a DC (direct current) voltage, the energy from which is stored in a storage device within the apparatus, and which further has the capability of being connectable to a source of electrical power for storing energy therefrom in the storage device for later consumption by a user to power an external electronic device connected to the energy harvesting apparatus.

In accordance with one form of the present invention, a device for harvesting energy from WIFI or other RF signals includes one or more broadband antennas which are respectively connected to one or more voltage multiplier/rectifier circuits. Each voltage multiplier/rectifier circuit converts the WIFI or RF signals received by the respective antenna coupled thereto into a DC voltage, having an amplitude multiplied a number of times, such as by a factor of 4, 6 or 8. The DC voltage output signals from the voltage multiplier/rectifier circuits are added in series and in the same polarity (i.e., the voltages are “stacked”) or in parallel to provide a combined, detected DC voltage signal, which is provided to a temporary storage device, such as a capacitor.

When the voltage on the capacitor reaches a predetermined level, a watchdog monitor circuit effectively connects the temporary storage capacitor to the input of a power management circuit. The power management circuit includes a charge pump circuit which increases the voltage on the input of the power management circuit to a higher, more useable voltage on its output for charging a storage device, such as a lithium battery (for example, lithium polymer, lithium-ion or any lithium chemical type). Accordingly, the output voltage of the power management circuit is at a predetermined voltage level to charge the lithium battery or other storage device.

In a preferred form of the present invention, the device further includes a solar cell which converts solar energy from light impinging thereon to an electrical voltage, which is also filtered and provided to a second power management circuit. The output of this second power management circuit also provides a voltage at a predetermined level to the lithium battery or other storage device in response to the voltage from the solar cell resulting from the light impinging thereon.

The output of the lithium battery or storage device is connected to the input of a DC/DC boost converter circuit, which provides preferably a 5 volt DC voltage on a USB output connector to which is connectable the external electronic device to be powered thereby or whose battery is to be charged.

In a preferred form of the invention, the energy harvesting device of the present invention may include an input connector for receiving a charging voltage from an external power source, such as another electronic device, or a power transformer for such device which is connected to a cigarette lighter of an automobile, or to an AC/DC adapter for connection to a 110 volt AC wall power receptacle, for example. The power signal from this external electrical power source is provided to the lithium battery or other storage device internal to the energy harvesting circuit so that the lithium battery or storage device may be charged thereby.

These and other objects, features and advantages of the present invention will be apparent from the following detailed description of illustrative embodiments thereof, which is to be read in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a block diagram of a circuit for harvesting energy transmitted from an RF (radio frequency) source to charge and/or power an electronic device, such as a cellular telephone or a PDA or a Blackberry™ device, formed in accordance with the present invention.

FIG. **2** is a schematic diagram of a first preferred form of an electrical circuit constructed in accordance with the present invention for harvesting energy from WIFI signals.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is designed to receive radio frequency signals from any WIFI 2.4 to 2.5 GHz source, WiMax, Satellite Radio, Cellular Phone (850 MHz to 900 MHz and 1.8 GHz-1.9 GHz), and UHF TV signals or CATV signals and convert the received radio frequency signal into another form of energy, such as a DC voltage. Even more preferably, the energy harvesting device of the present invention is capable of receiving RF signals from about 500 MHz to about 2.5 GHz, and convert the received signals into electrical energy. The same circuit configuration can also be designed and extended to convert RF signals in VHF, FM and UHF frequencies (such as signals from CATV) into DC electrical energy. This energy is utilized to recharge a battery inside any cell phone through a USB connector. The invention is designed to use WIFI signals, in particular, for energy harvesting because many WIFI signal transmitters are provided and are available in public places, such as airport terminals, coffee shops, fast food restaurants, etc., where an AC power outlet may not be easily accessible for a user to charge or power an electronic device by connecting it to the outlet.

There are many types of energy harvesting devices or systems that are known, such as solar cell, windmill, water pressure to provide movement in power generators, FM radio signals to charge small toys or flying devices (for example, spy monitor devices) inductive chargers, and the like. However, no one heretofore has taken advantage of the many WIFI signals, cell phone signals, Satellite Radio or UHF TV signals that are mostly available in public places, and the energy from those transmitted signals is wasted and not utilized. Such WIFI signals, Satellite Radio, UHF TV signals or cell phone signals are broadcast 24 hours a day, every day.

Most people think that the energy from WIFI or other high frequency radio signals is very minute and cannot be used, but the inventor has found otherwise. Generally, the present invention is directed to harvesting the WIFI, UHF TV, Satellite Radio or cell phone signals and converting the electromagnetic energy in the signals to a DC voltage, and providing a "top charge" to charge the batteries of an external electronic device connected thereto, or to continuously power an internal battery within the energy harvesting device until its storage capacity is full, and that battery energy may be reused when needed to power an electronic device, such as a cellular phone, PDA, MP3 player, camera or other electronic device connected thereto.

The present invention utilizes WIFI or cell phone signals that are available and easy to find in any public place or in a consumer's home almost anywhere in the world. There are many high powered WIFI broadcasting stations whose transmitted signals create a WIFI hotspot, and also WIMAX signals to be implemented at some future time are projected to be rather strong signals that have a 32 mile radial range, and the energy from these signals may also be harvested.

Provided above is a general description of the purpose and implementation of the energy harvesting method and apparatus of the present invention. Now, a detailed description of preferred forms of the present invention is provided.

A block diagram of a circuit for harvesting energy transmitted from an RF (radio frequency) source is shown in FIG. **1** of the drawings. An antenna **2**, such as patch antenna, receives an RF signal, such as a WIFI signal transmitted in public places, such as airport terminals, coffee shops, fast food restaurants and the like, and converts the RF signal to an electrical signal. This electrical signal is provided via a transmission line or signal cable **4** to a circuit **6** which rectifies and harvests the energy of the transmitted RF signal. This circuit **6** converts the RF electrical signal from the antenna **2** to a DC signal of sufficient magnitude to charge and/or power an electronic device **8**, such as a cellular telephone, a PDA or a Blackberry™ device connected to the energy harvesting and rectifier circuit **6** by a USB cable **10** or the like.

FIG. **2** is a schematic diagram of a first preferred form of an electrical circuit constructed in accordance with present invention for harvesting energy from WIFI or other RF signals. The energy harvesting circuit, in accordance with this first embodiment, includes an antenna **2** which receives RF signals, such as WIFI signals, and converts the RF signals to an electrical signal which is provided by a transmission line or cable **4** to the input of an RF-to-DC rectifier circuit **12**. The rectifier circuit **12** converts the RF signal to a DC (direct current) signal on its output. This DC signal is provided to a first storage device **14**, which is preferably a 2F (farad), 2.5 volt supercapacitor. The first storage device **14** stores and accumulates charge thereon from the rectified (DC) signal outputted by the rectifier circuit **12**.

The DC signal outputted by the rectifier circuit **12** is also provided to the input (Pin **3**) of a flash-based CMOS microcontroller **16** preferably having Part No. 12F683-0847 manufactured by Microchip Technology Inc. of Chandler, Ariz. The microcontroller **16** is used as a charge circuit control to prevent a lithium battery used as a second storage device **18** in the energy harvesting circuit from overcharging.

The voltage on the supercapacitor **14** is also provided to the input of a first stage DC-to-DC converter circuit **20**, which acts as a charge pump, or stated another way, a step up voltage regulator and battery management circuit. Preferably, the first stage DC-to-DC converter circuit **20** is Part No. MAX1672 manufactured by Maxim Integrated Products of Sunnyvale, Calif.

When the voltage on the supercapacitor **14** reaches a certain level, such as about 1.5 volts, which is provided to the input of the microcontroller **16**, the microcontroller **16** generates a pulsed signal on its output (Pin **5**), which is provided to the enable input of the first stage DC-to-DC converter circuit **20** to cause the converter circuit **20**, acting as a charge pump, to increase the voltage on its input from about 1.5 volts to about 4.5 volts on its output. If the voltage on the supercapacitor **14** is below a predetermined level, such as 1.5 volts, the microcontroller **16** does not provide a pulsed signal to the enable input of the first stage DC-to-DC converter circuit **20** to effectively cause the converter circuit **20** from operating, so as not to deplete charge on the supercapacitor **14** if the supercapacitor is insufficiently charged.

The output of the first stage DC-to-DC converter circuit **20** is provided to the input of a second stage DC-to-DC converter circuit **22**, preferably being the same integrated circuit as the first stage DC-to-DC converter circuit **20** and having Part No. MAX1672. Again, the preferred voltage on the output of the first stage DC-to-DC converter circuit **20** is about 4.5 volts.

As can be seen from FIG. **2**, the energy harvesting circuit also includes a USB charger port or connector **24** for providing a connection to an external source of voltage (preferably, about 5 volts DC), to charge the internal second storage device **18**, which as will be explained is preferably a lithium polymer battery, using a lap top computer or other device connectable to the USB charger connector **24**. The USB charger connector **24** has its +5 volt input pin connected to the connection between the output of the first stage DC-to-DC converter circuit **20** and the input of the second stage DC-to-DC converter circuit **22**.

The second stage DC-to-DC converter circuit **22** acts as a low drop out, step down voltage converter/regulator to convert the 4.5 volts from the first stage DC-to-DC converter circuit **20** (or the 5 volt DC signal provided on the USB charger connector **24** from an external source) to a 3.7 volt DC signal on the output of the second DC-to-DC converter circuit **22**. This output voltage of the second stage DC-to-DC converter circuit **22** is provided to the positive side of a lithium polymer battery **18** forming part of the energy harvesting circuit, the negative side of the battery being preferably grounded. Preferably, the lithium polymer battery is a 3.7 volt, 1.5 amp battery which is used as a second storage device **18** which is charged by the rectified and DC-converted voltage generated by the energy harvesting circuit from the RF signal received by the antenna **2**, or by an external DC power source connected to the USB charger connector **24**.

The voltage on the lithium polymer battery **18** is monitored so as not to exceed approximately 3.7 volts. The positive side of the lithium polymer battery **18** is connected to a feedback input (Pin **1**) on the microcontroller **16** in order to limit the voltage generated by the energy harvesting circuit provided to the lithium polymer battery **18** and to an external electronic device **8** connected to the energy harvesting circuit. When the voltage on the feedback input of the microcontroller **16** reaches a predetermined threshold voltage, such as 3.7 volts, the microcontroller **16** ceases providing a pulsed signal on its output (Pin **5**) connected to the enable input on the first stage DC-to-DC converter circuit **20** so as to prevent the first stage DC-to-DC converter circuit **20** from operating as a charge pump beyond a predetermined voltage conversion limit. When the voltage on the lithium polymer battery **18** falls to below the predetermined threshold voltage, which is provided to the feedback input of the microcontroller **16**, the microcontroller **16** again provides a pulsed signal on its output to the enable input of the first stage DC-to-DC converter circuit **20** so that the converter circuit **20** resumes operation as a charge pump to increase the input voltage provided thereon to approximately 4.5 volts. However, no pulsed signal will be provided to the enable input of the first stage DC-to-DC converter circuit **20** from the microcontroller **16** if the voltage on the supercapacitor **14** is below a predetermined threshold voltage, such as 1.5 volts.

The positive side of the lithium polymer battery **18** is connected through a user controlled single pole, single throw switch **26** to the input of a third stage DC-to-DC converter circuit **28**, also acting as a charge pump. The third stage DC-to-DC converter circuit **28** is preferably realized using an integrated circuit having Part No. TPS61200DRCT, manufactured by Texas Instruments of Dallas, Tex. The third stage DC-to-DC converter circuit **28** increases the voltage provided by the lithium polymer battery **18** (3.7 volts) to the input of the third stage DC-to-DC converter circuit **28** to approximately 5 volts DC on the output thereof. The output signal of the third stage DC-to-DC converter circuit **28** is provided to a particular pin (+5 volt DC pin) on a USB output connector **30**, having another certain pin grounded. An external electronic or electrical device **8**, such as a cellular phone, PDA, MP3 player, camera or the like, may be connected to the USB output connector **30** of the energy harvesting circuit using a standard USB cable **10** so that the energy harvesting circuit of the present invention may charge the batteries of the external electronic device **8** or power the external electronic device **8** connected to the energy harvesting circuit by the user.

Referring now to FIG. **3** of the drawings, a block diagram of a second preferred form of the electrical circuit of the energy harvesting device of the present invention is shown. Preferably, a plurality of broadband antennas **2**, each preferably the same, is used. In one form of the present invention, four broadband antennas **2***a*, **2***b*, **2***c*, **2***d* are used, and each broadband antenna **2***a*-**2***d* is particularly situated within the housing **32** for the energy harvesting circuit so that each antenna **2***a*-**2***d* will be capable of receiving WIFI or other RF signals which are transmitted no matter what disposition the housing **32** is in. Preferably, each broadband antenna **2***a*-**2***d* is capable of receiving signals from about 500 MHz to about 2.5 GHz.

Even more preferably, and as shown in FIGS. **5**-**10** of the drawings, there are four monopole broadband antennas **2***a*-**2***d* which are mounted on the inside surface of a transparent or translucent cover **34** of the housing **32**. The cover **34** is pivotally joined at one edge thereof to a corresponding lateral or top edge of the main body or base **36** of the housing **32**, so that it may be raised and lowered respectively away from and in proximity to the top surface of the main body or base **36**, thus covering and uncovering a solar cell **40** which is exposed through an opening formed in the top surface **38** of the main body or base **36**. Although the four monopole antennas **2***a*-**2***d* will receive RF energy when the cover **34** is disposed in its lower position, covering the solar cell **40** of the housing **32**, the four monopole antennas will more effectively receive RF energy transmitted from an RF source or WIFI source when the cover **34** is disposed in a raised position, such as shown in FIG. **5** of the drawings. The features of the housing **32** of the energy harvesting device of the present invention will be described in greater detail.

Each antenna **2***a*-**2***d* of the plurality of antennas is coupled to a respective voltage multiplier/full wave rectifier circuit **42**, as shown in FIG. **3**. More specifically, each voltage multiplier/rectifier circuit **42** includes a voltage multiplier so that the WIFI or RF signals received by the respective antenna **2***a*-**2***d* coupled thereto is converted into a DC voltage having an amplitude multiplied a number of times, such as by a factor of 4, 6 or 8, for example.

More specifically, the first antenna **2***a* is coupled to the first multiplier/rectifier circuit **42***a*, which converts the WIFI or RF signals the first antenna **2***a* receives into a DC voltage multiplied by a factor of 4, 6, or 8, for example. The DC output voltage of the first multiplier/rectifier circuit **42***a*, as a result of the detected signal of the first antenna **2***a* coupled thereto, is provided to node A and a first leg of a capacitor C**39** (see FIG. **3**).

The second multiplier/rectifier circuit **42***b* is very similar to the first multiplier/rectifier circuit **42***a*. The second multiplier/rectifier circuit **42***b* converts to a DC voltage the WIFI or RF signals received by the second antenna **2***b* coupled to it, multiplied by a desired factor (e.g., 4, 6 or 8), and this voltage is provided to node B and a first leg of a capacitor C**34**, whose second leg is connected to node A and the first leg of capacitor C**39**. Thus, the output voltage of the second multiplier/rectifier circuit **42***b* is effectively stacked on top of the voltage outputted by the first multiplier/rectifier circuit **42***a*.

The third multiplier/rectifier circuit **42***c* is similar to the second multiplier/rectifier circuit **42***b*, and it is coupled to the third antenna **2***c* in the same manner that the first and second multiplier/rectifier circuits **42***a*, **42***b* are respectively coupled to the first and second antennas **2***a*, **2***b*. Again, the DC voltage outputted by the third multiplier/rectifier circuit **42***c*, which is provided to node C and the first leg of a capacitor C**21**, whose second leg is connected to node B and the first leg of capacitor C**34**, is stacked on top of the DC voltages provided by the first and second multiplier/rectifier circuits **42***a*, **42***b*.

The fourth multiplier/rectifier circuit **42***d* is similar to the third and second multiplier/rectifier circuits **42***c*, **42***b* described previously, and is coupled to the fourth antenna **2***d*. The DC voltage outputted by the fourth multiplier/rectifier circuit **42***d* is provided to node D and the first leg of a capacitor C**12**, whose second leg is connected to node C and the first leg of capacitor C**21**. As a result of RF signals received by the fourth antenna **2***d* coupled to the fourth multiplier/rectifier circuit **42***d*, the DC output voltage of the fourth multiplier/rectifier circuit **42***d* is stacked on top of the DC voltages outputted by the third, second and first multiplier/rectifier circuits **42***c*, **42***b*, **42***a*. Thus, the potential at the first leg of capacitor C**12**, measured with respect to the second leg of capacitor C**39**, could be as much as, or possibly more than, 25 volts DC as a result of the stacked arrangement of output voltages from the first, second, third and fourth multiplier/rectifier circuits **42***a*-**42***d*. As will be explained in greater detail, the second leg of capacitor C**39** is coupled to a "jump start" battery BT**2** (also referred to as a jump start voltage device **44**, and the stacked output voltages from the four multiplier/rectifier circuits **42***a*-**42***d* are raised by the DC voltage provided by battery BT**2**.

The combined stacked voltage generated by the interconnected multiplier/rectifier circuits **42***a*-**42***d* is provided to a capacitor C**3**. Capacitor C**3** acts as a temporary storage device **14** for the voltages detected and rectified by the four multiplier/rectifier circuits **42***a*-**42***d* as a result of RF energy received by the four receiving antennas **2***a*-**2***d*. More specifically, the first leg of capacitor C**3** is connected to the first leg of capacitor C**12** and the second leg of capacitor C**3** is grounded. Preferably, capacitor C**3** is a low leakage tantalum capacitor, although other storage devices and types of capacitors may be used.

As mentioned previously, capacitor C**3** is provided for the temporary storage of the stacked DC voltage outputted by the four multiplier/rectifier circuits **42***a*-**42***d*, as a result of RF or WIFI energy received by the four antennas **2***a*-**2***d* connected thereto, as well as the DC voltage of the jump start battery BT**2** which raises the stacked voltage at node D.

The circuit of the present invention also preferably harvests light energy by using a solar cell **40** and circuit. In this regard, reference should continue to be had to FIG. **3** of the drawings. A solar cell **40** is provided in the energy harvesting device of the present invention and is exposed through an opening in the top surface **38** of the main body or base **36** of the housing **32** of the energy harvesting device. The solar cell **40** can generate between about 3.1 volts with indoor lighting and about 5.5 volts in direct sunlight. The negative terminal of the solar cell **40** is preferably grounded, and the positive terminal of the solar cell **40** is connected to the cathode of a zener diode D**2**, whose anode is connected to ground. Preferably, zener diode D**2** is a 5.6 volt zener diode to limit the output voltage provided by the solar cell **40** so as not damage any circuitry connected thereto.

The output of the solar cell **40** is connected to the VDD input of a power management integrated circuit **46**, such as Part No. CBC3112 manufactured by Cymbet Corporation of Elk River, Minn., or any similar power management circuit made by a number of manufacturers. The output voltage of the power management circuit **46**, which is regulated and selected to be about 4.2 volts, is provided through an isolation diode D**3** to the positive side of the main energy storage battery BT**1** (i.e., second or main storage device **18**) to help maintain the charge on battery BT**1** when no or negligible WIFI or RF signals are present or can be detected and when ambient light conditions permit the charging of battery BT**1** by the solar cell **40**.

To help "jump start" or boost the charge on the temporary storage capacitor C**3**, a 3.7 volt, 60 milliampere-hour or greater, lithium polymer battery BT**2** is used (see FIG. **3**). The negative side of battery BT**2** is grounded, while the positive side is coupled to the second leg of capacitor C**39** in order to raise the stacked voltage generated by the four interconnected multiplier/rectifier circuits **42***a*-**42***d* by 3.7 volts, i.e., the voltage of battery BT**2**. Accordingly, the voltage across capacitor C**3** is the voltage resulting from the combination of the voltage from battery BT**2** and the RF or WIFI energy harvested by the circuit of the present invention. It should be noted that the 25 volt DC signal resulting from the stacked arrangement of the four multiplier/rectifier circuits **42***a*-**42***d* is an unloaded voltage, and when used under load to charge capacitor C**3**, the voltage drops significantly.

The voltage from battery BT**2** is used to boost the voltage temporarily stored on **42***d* capacitor C**3** and to supplement the voltage outputted by the four multiplier/rectifier circuits **42***a*-**42***d* resulting from the WIFI and RF energy which is harvested. Furthermore, the "boost" voltage from battery BT**2** helps insure that a second power management circuit **48** (see FIG. **3**) has a sufficient voltage on its VDD input in order to operate.

It is estimated that a 60 milliampere-hour battery used as battery BT**2** will last for approximately 1500 hours, or about 62 days, when the energy harvesting device of the present invention is stored in a dark room, thus with no voltage being generated by the solar cell **40**, as the circuit draws only about 25 microamperes to about 40 microamperes of current from battery BT**2**.

To maintain the charge on battery BT**2**, the output voltage generated by the power management circuit **46** is provided to the anode of an isolation diode D**50**, whose cathode is connected to the positive side of battery BT**2**. In this way, the power management circuit **46** acts as a buffer between the solar cell and battery BT**2** to prevent battery BT**2** from overcharging, which may result in the battery overheating.

Alternatively, to charge battery BT**2**, the positive lead of the solar cell **40** may be coupled to the positive side of battery BT**2** through a diode (not shown), the anode of the diode being connected to the positive lead of the solar cell **40**, and the cathode of the diode being connected to the positive side of battery BT**2**. Optionally, a PTC (positive temperature coefficient) thermistor (not shown) may be connected to battery BT**2** between the solar cell **40** and the battery BT**2** to provide some protection to the circuit in the remote chance that battery BT**2**, which is preferably a lithium polymer battery, overheats due to overcharging or short circuiting.

Referring again to FIG. **3** of the drawings, it will be seen that a second power management circuit **48** is provided, and is indirectly coupled to the temporary storage capacitor C**3**. Preferably, a watchdog monitor circuit **50** is disposed between capacitor C**3** and the VDD input of the power management circuit **48**, as will be explained in greater detail. Power management circuit **48** may be Part No. CBC3112 manufactured by Cymbet Corporation of Elk River, Minn., or any similar power management circuit made by a number of manufacturers. The VBAT output of the power management circuit **48** is connected to the anode of diode D**1**, as will be explained in greater detail.

Since the power management circuit **48**, like the power management circuit **46**, requires about 2.6 volts on its VDD input in order to operate, the energy harvesting circuit of the present invention preferably includes a watchdog monitor circuit **50** situated between the temporary storage capacitor C**3** and the power management circuit **48** in order to minimize the unnecessary discharge of energy stored in capacitor C**3** when there is insufficient voltage on capacitor C**3** for the power management circuit **48** to operate. The watchdog monitor circuit **50** may include a voltage detector circuit **52** and a transistor switch circuit **54** connected thereto and controlled thereby. The voltage detector circuit **52** may be a constant voltage power monitor with hysteresis and having Part No. S-80825 manufactured by Seiko Instruments, Inc. of Chiba, Japan.

The watchdog monitor circuit **50** comprising the voltage detector circuit **52** and the transistor switch circuit **54** is used to minimize any leakage from the temporary storage capacitor C**3** by preventing a direct connection between capacitor C**3** and the VDD input of the second power management circuit **48** when the voltage on the temporary storage capacitor C**3** is below a predetermined voltage. More specifically, when the voltage is below about 2.6 volts on capacitor C**3**, the voltage detector circuit **52** of the watchdog monitor circuit **50** provides an output signal to the transistor switch circuit **54** to open the transistor switch circuit **54** and prevent the voltage on capacitor C**3** from being connected therethrough to the VDD input of the second power management circuit **48** so that circuit **48** does not drain the energy from the WIFI or RF energy harvesting circuit stored on capacitor C**3**. However, if the voltage on capacitor C**3** rises above about 2.6 volts, the voltage detector circuit **52** of the watchdog monitor circuit **50** outputs a signal to close the transistor switch circuit **54** so that the voltage on capacitor C**3** is provided to the VDD input of the second power management circuit **48**. Typically, the voltage on the temporary storage capacitor C**3** will range between about 2.5 volts and about 2.65 volts, and only when this voltage is equal to or above about 2.6 volts will capacitor C**3** be effectively connected to the input of the second power management circuit **48**. A general form of the watchdog monitor circuit **50** described above may be found in the application notes accompanying the data sheet of the S-808xxC series of voltage detectors disseminated by Seiko Instruments Inc. (see FIGS. **14** and **20** thereof).

The power management circuit **48** has a charge pump which converts the 2.6-2.65 voltage (or, more specifically, any voltage above 2.63 volts) on its input to between about 4.1 volts DC and about 4.2 volts DC on its VBAT output. The VBAT output of the second power management circuit **48** is connected to the anode of a low voltage drop (about 0.1 volts) isolation diode D**1**. The cathode of diode D**1** is connected to the positive side of a 3.7 volt, 1000 milliampere-hour, lithium polymer battery BT**1**, which acts as the main energy storage battery or device **18**.

Preferably, a battery protection circuit **56** is connected to the battery BT**1** to provide overcharge protection and over-discharge protection. The battery protection circuit **56** is preferably Part No. DW01 manufactured by Fortune Semiconductor Corporation of Taipei, Taiwan, which monitors the voltage on the positive side of battery BT**1**, and drives a transistor switch circuit **58** situated between the negative side of the battery and ground to selectively connect and disconnect the negative side of battery BT**1** to and from ground.

When the voltage on the lithium battery BT**1** exceeds a certain predetermined overcharge protection voltage, charging of battery BT**1** is inhibited by the battery protection circuit **56** opening the transistor switch circuit **58** to disconnect the battery BT**1** from ground. On the other hand, when the voltage of the lithium battery BT**1** falls below a predetermined over-discharge protection voltage, discharging of battery BT**1** is inhibited by the battery protection circuit **56** opening the transistor switch circuit **58** to disconnect the battery BT**1** from ground. Essentially, the negative side of battery BT**1** is disconnected from ground when either an overcharge condition or an over-discharge condition exists. When neither condition exists, the battery protection circuit **56** closes the transistor switch circuit **58** to connect the negative side of the battery BT**1** to ground.

The energy harvesting circuit of the present invention also preferably includes a battery charge monitoring circuit **60** to provide an indication to the user of the energy harvesting device whether the lithium battery BT**1** is sufficiently charged to power an external electronic device **8** connected to the energy harvesting circuit or to charge the battery or batteries of the external device. Preferably, the battery charge monitoring circuit **60** includes a voltage divider network (having interconnected resistors) (not shown) operatively coupled to the positive side of the battery BT**1** and used to bias a transistor (not shown) on or off, depending on the voltage of the battery. A single pole, single throw (or equivalent) momentary push button switch SW**2** (or switch circuit) is connected between the positive side of the lithium battery BT**1** and the battery charge monitoring circuit **60**, and is preferably mounted on the top surface **38** of the housing **32** so as to be accessible to the user of the energy harvesting device. Accordingly, so as not to drain the charge from battery BT**1**, the battery charge monitoring circuit **60** will only work when the user presses on momentary push button switch SW**2** to provide power to the battery charge monitoring circuit **60**.

A dual color (red/green) light emitting diode (LED) or separate red and green LEDs **62**, **64** are operatively coupled to and driven by the battery charge monitoring circuit **60**, and are preferably mounted on the top surface **38** of the housing **32**, or elsewhere on the housing, to be viewable by the user of the energy harvesting device.

When the voltage on battery BT**1** is 3.3 volts or greater, the battery charge monitoring circuit **60** will cause the green LED **64** to light when the user presses on momentary push button switch SW**2**. If the voltage on battery BT**1** is 3.0 volts or lower, the battery charge monitoring circuit **60** will cause the red LED **62** to illuminate when the user presses on momentary push button switch SW**2**. The 3.3 volt threshold and the 3.0 volt threshold may be adjusted by changing the values of resistors from which the voltage divider network is formed to turn the transistor on or off at different voltage levels.

As shown in FIG. **3**, a single pole, single throw switch or switch circuit SW**1** has one side connected to the positive side of the lithium polymer battery BT**1** or other storage device. The switch or switch circuit SW**1** is provided to ensure that stored energy is not drawn from the battery until desired by the user. As will be explained in greater detail, the switch SW**1** is coupled to a spring biased, sliding cover **66** on the housing **32** for the energy harvesting circuit (see FIG. **10**) that selectively covers an output USB type A connector **30**, and will be automatically activated to provide electrical conduction therethrough when the user slides the USB connector cover **66** in one direction on the main body or base **36** of the housing **32**.

The other side of the switch or switch circuit SW**1** is connected to the input of a DC/DC boost converter circuit **28**, which may be an integrated circuit having Part No. TPS61200DRCT, manufactured by Texas Instruments of Dallas, Tex. This DC/DC converter circuit **28** is configured with external components to convert the 3.7 volts of the lithium polymer battery BT**1** to a 5 volt DC output.

A 5 volt DC regulated voltage is preferably provided by the DC/DC boost converter circuit **28** to the USB connector **30** of the energy harvesting circuit to which an external electronic device **8** is connectable. Preferably, pin **1** (VCC) of the output connector **30** provides a 5 volt DC output signal to the external electronic device **8**. As shown in FIG. **10** of the drawings, USB output connector or port **30** is preferably positioned on one of the narrower sides **68** of the housing **32** of the energy harvesting device.

Thus, the circuit configuration described above will allow the output of this USB type A connector **28** to be able to provide the correct charge voltage and current for iPhone™, iPod™ and iPad™ devices, which are manufactured by Apple, Inc. Also, this circuit configuration will be compatible and provide correct charge voltage and current to most if not all smart phones, PDAs, MP3 players and Blackberry™ devices.

As mentioned previously, the energy harvesting device of the present invention may include an input connector **24** for receiving a charging voltage from an external power source, such as another electronic device, or a power transformer which may be connected to a cigarette lighter of an automobile, or may be an AC/DC adapter which is connectable to a standard house wall outlet, for example. The power signal from this external electrical power source is provided to the anode of an isolation diode D**4**, whose cathode is in electrical communication with the positive side of the lithium battery BT**1** or other storage device internal to the energy harvesting circuit so that the lithium battery or storage device may be charged thereby.

More specifically, and as shown in FIGS. **3** and **9** of the drawings, a mini USB connector **24** is provided on one side (preferably on one of the narrower sides **68** not occupied by output USB connector **30**) of the housing **32** of the energy harvesting device. Input connector **24** is provided so that the user may connect to connector **24** an AC/DC wall outlet adapter, or another adapter or transformer which is connectable to an auxiliary power outlet or cigarette lighter in an automobile, or to an output port providing a 5 volt DC output signal of an electronic device, such as a laptop computer. Preferably, pin **1** (VCC) of connector **24** provides a 5 volt DC input signal to the circuit.

The 5 volt DC input signal on connector **24** is provided to the anode of isolation diode D**4**. The cathode of diode D**4** is electrically connected directly or through a resistor (not show) to the positive side of the lithium battery BT**1** so that the lithium battery of the energy harvesting circuit may be charged externally by the AC/DC adapter, power transformer, automobile power outlet, laptop computer or the like connected to the mini USB connector **24**.

Also, with an external power source connected to the input USB connector **24**, and with switch SW**1** in a closed position, the external power source will provide power to the output USB connector **30** and to an external electronic device **8** coupled thereto.

Referring now to FIGS. **5**-**10** of the drawings, it will be seen that a preferred form of the housing **32** for the energy harvesting circuit includes a main body or base **36** which is rectangular in shape overall, and a transparent or translucent cover **34** that is pivotally joined to a longer edge (or, alternatively, a narrower edge) of the top surface **38** of the main body **36**. The solar cell **40** is mounted on the top surface **38** of the main body **36** or through a window formed through the thickness of the main body so as to be exposed to ambient light. The transparent cover **34** is pivotable on the top surface **38** between a closed position, where it covers the top surface **38** or at least the solar cell **40** mounted on the top surface, and an open position, where it is raised from the top surface **38** of the main body **36** to a position which is substantially perpendicular to the plane in which the top surface **38** of the main body resides. Thus, if the bottom surface **70**, which is opposite the top surface **38**, of the main body **36** rests on a horizontal supporting surface, such as a table or desk, then the transparent cover **34** may be pivoted to a substantially vertical position.

As mentioned previously, there are preferably four antennas **2***a*-**2***d* which are spaced apart from each other a predetermined distance, which are mounted to the transparent cover **34** on the inside surface thereof. For best WIFI or RF signal reception, it is preferred that these broadband antennas **2***a*-**2***d*, preferably being monopole antennas, are disposed in a vertical position. As such, it is preferred if the user of the energy harvesting device of the present invention raises the transparent cover **34** to a vertical position when he chooses to charge the internal battery BT**1** of the energy harvesting circuit with WIFI or RF signals present in the location where the energy harvesting device is situated.

Preferably, the cover **34** is transparent or translucent, as mentioned previously, so that the solar cell **40** of the energy harvesting circuit will receive light energy through the cover **34** to charge the internal lithium battery BT**1**, even if the cover **34** is in a closed position.

Also, as mentioned previously, so as not to discharge the internal lithium battery BT**1** unnecessarily when no external electronic device **8** is being powered by the energy harvesting circuit, a sliding cover **66** is provided over the output USB connector **30**, and the switch SW**1** is operatively coupled to, and activated by, movement of the USB connector sliding cover **66**.

More specifically, the USB output connector **30** is preferably situated on a smaller side **68** of the main body **36** of the housing **32** opposite that of the input USB connector **24** (although the connectors **30** and **24** could be mounted on opposite wider sides **72** of the housing **32**). There is a small cover **66** for the output USB connector **30** so that a user may slide this cover **66** and connect the output USB connector **30** to an external electronic device **8** in order to power or recharge the batteries of the external electronic device. When the sliding cover **66** is positioned such that it uncovers the output USB connector **30**, it automatically engages and activates the single pole, single throw switch or switch circuit SW**1** so that the battery BT**1** or other storage device is electrically connected to the input of the DC/DC boost converter **28** to provide a 5 volt output voltage on the output USB connector **30**.

When the sliding cover **66** is returned to its closed position, covering the output USB connector **30**, it deactivates the switch or switch circuit SW**1**, breaking the connection between the lithium battery BT**1** or other storage device within the energy harvesting circuit and the DC/DC converter circuit **28**, so that no power is provided to the output USB connector **30**. The sliding cover **66**, in this closed position, covers the output USB connector **30** to prevent access thereto. In a preferred form of the present invention, the sliding cover **30** may be biased by a spring (not shown) so that it automatically returns to a closed position, covering the output connector **30** and deactivating switch SW**1**, when no external electronic device **8** is connected to output connect or connector **30** of the energy harvesting device.

The purpose of having the sliding cover **66**, covering and uncovering the output USB connector **30**, is to minimize any energy drain from the lithium battery BT**1** when there is no need to provide power to an external electronic device **8**. It should be realized that the user controlled switch **26** mounted on the top surface **38** of the base **36** may be omitted if the sliding cover **66** coupled to switch SW**1** to activate switch SW**1** is used. Alternatively, the switch labeled with reference number **26** shown in FIGS. **5-10** may instead be used as switch SW**2**, which may be a momentary push button switch, which the user presses to momentarily activate the battery charge monitoring circuit **60** to illuminate the red LED **62** or the green LED **64** so as to minimize any drain on the lithium battery BT**1**.

In one form of the present invention, the four antennas **2***a*-**2***d* are identical to one another and have the same or similar broadband bandwidth characteristics. In an alternative form of the present invention, the energy harvesting circuit may include several narrow band antennas **2**, such as one UHF antenna to receive signals in the range from between about 500 MHz and about 700 MHz, one cell phone and 900 MHz antenna to receive signals in the range from between about 850 MHz and about 928 MHz, one GSM band antenna to receive signals in the range from between about 1.8 GHz and about 1.9 GHz, and one WiFi/WiMAx/Satellite radio antenna to receive signals in the range from between about 2.3 GHz and about 2.5 GHz, each antenna **2** being connected to a respective multiplier/rectifier circuit **42** through a coaxial cable **4** (see FIG. **9**).

Reference should now be had to FIGS. **4** and **11** of the drawings, which show another (third) preferred embodiment of the energy harvesting device of the present invention. The circuit shown in the schematic diagram of FIG. **4** is similar in many respects to the circuit shown in FIG. **3**. However, in this preferred form, there are six (6) antennas **2***a*-**2***f* provided (also as shown in FIG. **10**) and six (6) multiplier/rectifier circuits **42***a*-**42***f*. Therefore, there are nodes A-F associated with the outputs of the first multiplier/rectifier circuit **42***a* through the sixth multiplier/rectifier circuit **42***f*, respectively.

In this alternative embodiment of the circuit shown in FIG. **4**, the output voltages from the first multiplier/rectifier circuit **42***a* and the second multiplier/rectifier circuit **42***b* are stacked together in series on top of the voltage of the jump start battery BT**2**, and the stacked voltage of the first multiplier/rectifier circuit **42***a* and the second multiplier/rectifier circuit **42***b* is provided at node B and to the temporary storage capacitor C**3** through a diode D**60**, whose anode is connected to node B and whose cathode is connected to temporary storage capacitor C**3**.

Similarly, the output voltages of the third multiplier/rectifier circuit **42***c* and the fourth multiplier/rectifier circuit **42***d* are stacked in series on the voltage of the jump start battery BT**2**. The stacked voltage of the fourth multiplier/rectifier circuit **42***d* and the third multiplier/rectifier circuit **42***c* is provided at node D and to the temporary storage capacitor C**3** through diode D**62**, whose anode is connected to node D and whose cathode is connected to the temporary storage capacitor C**3**.

In the same manner, the output voltage of the fifth multiplier/rectifier circuit **42***e* and the output voltage of the sixth multiplier/rectifier circuit **42***f*, whose inputs are respectively connected to the fifth antenna **2***e* and the sixth antenna **2***f*, are stacked in series on the voltage of the jump start battery BT**2**. The stacked voltage of the sixth multiplier/rectifier circuit **42***f* and the fifth multiplier/rectifier circuit **42***e* is provided at node F (node E is the output voltage at the fifth multiplier/rectifier circuit **42***e*) and is provided to the temporary storage capacitor C**3** through diode D**64**, whose anode is connected to node F and whose cathode is connected to the temporary storage capacitor C**3**.

More specifically, the positive side of the jump start battery BT**2** is connected to a first leg of each of capacitors C**39**, C**21** and C**100**. The second leg of each of capacitors C**39**, C**21** and C**100** is respectively connected to node A and capacitor C**34** (and the output of the first multiplier/rectifier circuit **42***a*); node C and capacitor C**12** (and the output of the third multiplier/rectifier circuit **42***c*); and node E and the first leg of capacitor C**102** (and the output of the fifth multiplier/rectifier circuit **42***e*). The second leg of capacitor C**102** is coupled to node F, the anode of diode D**64** and the output of the sixth multiplier/rectifier circuit **42***f*.

In other words, the outputs of the first and second multiplier/rectifier circuits **42***a*, **42***b* are connected in series, the outputs of the third and fourth multiplier/rectifier circuits **42***c*, **42***d* are connected in series, and the outputs of the fifth and sixth multiplier/rectifier circuits **42***e*, **42***f* are connected in series, to form three groups, and the output voltages of the series-connected groups are effectively connected in parallel with each other and provided to the temporary storage capacitor C**3**. This provides approximately 8-12 volts to charge the temporary storage capacitor C**3**, but at greater current capacity (because of the parallel arrangement of multiplier/rectifier groups) than having the outputs of the individual multiplier/rectifier circuits **42***a*-**42***f* all connected in series in a stack.

It should be realized that a greater or fewer number of parallel-connected groups of series-connected multiplier/rectifier circuits **42***a*-**42***f* may be used to generate the voltage to charge the temporary storage capacitor C**3**. For example, the third group consisting of the fifth and sixth multiplier/rectifier circuits **42***e*, **42***f*, and the corresponding fifth and sixth antennas **2***e*, **2***f* to which the fifth and sixth multiplier/rectifier circuits **42***e*, **42***f* are respectively connected, may be omitted to satisfy space constraints in the arrangement of the antennas **2** on the housing **32** of the energy harvesting device and to provide sufficient separation between adjacent antennas **2** in order to minimize any cross-coupling of the antennas.

This alternative circuit of the energy harvesting device of the present invention also includes a 6 volt DC, 2 amp (or the like) input connector **74**, which allows the main energy storage battery BT**1** to be charged up to approximately 75 percent of its capacity in about 30 minutes. As can be seen from FIG. **4** of the drawings, the output voltage on the quick charge connector **74** is provided to the main energy storage battery BT**1** through diode D**68**, whose anode is operatively connected to the output of connector **74** and whose cathode is operatively connected to the main energy storage battery BT**1**. Also, the output voltage on quick charge connector **74** is provided to the jump start battery BT**2** to charge that battery as well, through diode D**66**, whose anode is operatively connected to the output of the connector **74** and whose cathode is operatively connected to the positive side of jump start battery BT**2**.

Furthermore, the 5 volt DC connector **24** provides a charging voltage to the main energy storage battery BT**1** through diode D**4**, as mentioned previously with the circuit shown in FIG. **3**, but also provides a charging voltage to the jump start battery BT**2** through diode D**70**, whose anode is operatively connected to the output of connector **24** and whose cathode is operatively connected to the positive side of jump start battery BT**2**.

Similarly, the output voltage of the power management circuit **46**, which is derived from the solar cell voltage, is provided through diode D**3** to the main energy storage battery BT**1** and through diode D**50** to the positive side of jump start battery BT**2**, in the same manner as shown in the schematic diagram for the circuit shown in FIG. **3**.

With reference to FIG. **11** of the drawings, it can be seen that the six (6) antennas **2***a*-**2***f* are arranged side-by-side on the cover **34** of the housing **32**, which may be raised from the base **36** of the housing vertically so as to optimize the reception capabilities of the antennas. Although in FIG. **11** the six antennas **2***a*-**2***f* are shown mounted on the cover **34** transversely along the narrower side of the cover, which is hingedly joined to the base **36** of the housing **32**, it is envisioned to be within the scope of the present invention to arrange the six antennas **2***a*-**2***f* along the longer side of the cover **34** and having the longer side of the cover hingedly mounted to the longer side **72** of the base **36** of the housing **32** to provide a greater distance between adjacent antennas **2***a*-**2***f* and to minimize or eliminate any possible coupling between adjacent antennas.

The energy harvesting circuit of the present invention, in its preferred form, detects WIFI signals, WiMax, Satellite Radio, Cellular Phone (850 MHz to 900 MHz and 1.8 GHz-1.9 GHz), any 2.4 GHz and UHF TV signals and light to harvest energy therefrom to charge an internal battery BT**1** or other storage device for use on demand to power or recharge the batteries of an external electronic device **8** connected thereto. When not in use, the energy which is detected and harvested is stored in the battery BT**1** or other storage device so that the battery or other storage device is fully charged and ready to power an external electronic device **8** when connected thereto by the user.

It should be further realized that the energy harvesting device or at least portions of the electrical circuit thereof may be incorporated directly into a cellular phone, PDA, camera, Blackberry™ device or other electronic device **8** to power the device or charge the batteries thereof, without using a stand alone energy harvesting device within a separate housing **32**, such as shown in FIGS. **5-11**. The antenna or antennas **2**, and the solar cell **40**, of the energy harvesting device may be mounted on or within the housing of the electronic device to receive transmitted RF signals and light energy, respectively, in order to power the electronic device **8** or charge the batteries thereof. It is also envisioned to be within the scope of the present invention to incorporate the electrical circuit of the energy harvesting device directly on or in the battery used to power the electronic device **8**.

The various embodiments of the energy harvesting device of the present invention will now further be described in detail.

In one form of the present invention, an energy harvesting device preferably includes an antenna **2** for receiving a transmitted radio frequency (RF) signal, a rectifier circuit **6** operatively coupled to the antenna **2**, the rectifier circuit **6** converting the RF signal received by the antenna **2** to a direct current (DC) voltage, and an output connector **30** operatively coupled to the rectifier circuit **6** and providing the DC voltage thereon, an electronic device **8** being connectable to the output connector **30** for receiving the DC voltage provided on the output connector **30**.

In another form of the present invention, an energy harvesting device preferably includes an antenna **2** for receiving a transmitted radio frequency (RF) signal, the antenna **2** converting the received RF signal to an RF electrical signal, an RF-to-DC rectifier circuit **12**, the RF-to-DC rectifier circuit **12** being operatively connected to the antenna **2** and converting the RF electrical signal to a direct current (DC) voltage, and a first storage device **14**, the first storage device **14** being operatively connected to the RF-to-DC rectifier circuit **12** and being provided with the DC voltage and being charged thereby. The energy harvesting device preferably further includes a microcontroller **16**, the microcontroller **16** having a first signal input operatively connected to the first storage device **14** to monitor the DC voltage on the first storage device **14**, the microcontroller **16** generating a pulsed output signal if the DC voltage on the first storage device **14** is above a first pre-determined voltage level, a first stage DC-to-DC voltage converter circuit **20**, the first stage DC-to-DC voltage converter circuit **20** being operatively connected to the first storage device **14** and generating an output DC voltage which is greater than the DC voltage on the first storage device **14**, and a second stage DC-to-DC voltage converter circuit **22**, the second stage DC-to-DC voltage converter circuit **22** being operatively connected to the first stage DC-to-DC voltage converter circuit **20** and generating an output DC voltage which is less than the output DC voltage generated by the first stage DC-to-DC voltage converter circuit **20**. The energy harvesting device preferably further includes a second storage device **18**, the second storage device **18** being operatively connected to the second stage DC-to-DC voltage converter circuit **22** and being provided with the output DC voltage generated by the second stage DC-to-DC voltage converter circuit **22** and being charged thereby, a third stage DC-to-DC voltage converter circuit **28**, the third stage DC-to-DC voltage converter circuit **28** being operatively connected to the second storage device **18** and generating an output DC voltage which is greater than the DC voltage on the second storage device **18**, and an output connector **30**, the output connector **30** being operatively connected to the third stage DC-to-DC voltage converter circuit **28** and providing the output DC voltage generated by the third stage DC-to-DC voltage converter circuit **28** thereon. An electronic device **8** is connectable to the output connector **30** for receiving thereon the output DC voltage provided to the output connector **30**.

The energy harvesting device described above may further include an input connector **24**. The input connector **24** is operatively connected to the second stage DC-to-DC voltage converter circuit **22**. An external source of DC voltage is connectable to the input connector **24** for providing the DC voltage from the external source to the second stage DC-to-DC voltage converter circuit **22**. The second stage DC-to-DC voltage converter circuit **22** generates the output DC voltage of the second stage DC-to-DC voltage converter circuit **22** in response to the DC voltage from the external source provided on the input connector **24**.

In a preferred form of the invention, the first storage device **14** of the energy harvesting device includes a capacitor. In a preferred form of the invention, the second storage device **18** of the energy harvesting device includes a battery.

Preferably, the microcontroller **16** includes a second signal input operatively connected to the second storage device **18** to monitor the DC voltage on the second storage device **18**. The microcontroller **16** does not generate the pulsed output signal if the DC voltage on the second storage device **18** is above a second predetermined voltage level.

Another preferred form of the energy harvesting device is described as follows. The energy harvesting device includes a plurality of antennas **2** for receiving a transmitted radio frequency (RF) signal. The antennas **2** generate RF electrical signals in response to the transmitted RF signals received thereby. A plurality of multiplier and rectifier circuits **42** is also included. Each multiplier and rectifier circuit **42** is responsive to a respective RF electrical signal generated by an antenna **2** of the plurality of antennas and generates a direct current (DC) voltage in response thereto. At least some of the DC voltages are stacked in series to provide a combined DC voltage, the combined DC voltage being greater in magnitude than each individual DC voltage generated by a respective multiplier and rectifier circuit **42**.

The energy harvesting device of this preferred embodiment further includes a temporary storage device **14**. The temporary storage device **14** is responsive to the combined DC voltage and provides a temporarily stored DC voltage in response thereto. The temporary storage device **14** may be or include a capacitor. A first power management circuit **46** is also preferably included, the first power management circuit **46** being responsive to the temporarily stored DC voltage and generating a DC charging voltage in response thereto.

The energy harvesting device further preferably includes a main energy storage device **18**. The main energy storage device **18** is responsive to the DC charging voltage generated by the first power management circuit **46** and provides a main energy storage DC voltage in response thereto. The main energy storage device **18** may be or include a battery, such as a lithium polymer battery. An output connector **30** is also preferably included in the device, the output connector **30** providing an output connector DC voltage thereon in response to the main energy storage DC voltage. An electronic device **8** is connectable to the output connector **30** for receiving thereon the output connector DC voltage provided on the output connector **30**.

In another preferred form of the present invention, the energy harvesting device may further include a jump start DC voltage device **44**. The jump start DC voltage device **44** provides a jump start DC voltage. The combined DC voltage includes the at least some of the DC voltages generated by the plurality of multiplier and rectifier circuits **42** stacked in series and the jump start DC voltage, if such a jump start DC voltage device **44** is included. The jump start DC voltage device **44** may be or include a battery.

An input connector **24** may be included in the energy harvesting device described above. The input connector **24** is connectable to a source of DC voltage external to the energy harvesting device, the DC voltage of the external source being provided to at least one of the main energy storage device **18**, the jump start DC voltage device **44** and the output connector **30**.

The energy harvesting device described above may also include a DC-to-DC voltage converter circuit **28**. The DC-to-DC voltage converter circuit **28** is responsive to the main energy storage DC voltage and generates an output DC voltage in response thereto. The output connector **30** provides the output connector DC voltage in response to the output DC voltage generated by the DC-to-DC voltage converter circuit **28**, if such is included.

The energy harvesting device also preferably includes a watchdog monitor circuit **50**. The watchdog monitor circuit **50** is responsive to the temporarily stored DC voltage and selectively provides the temporarily stored DC voltage to the first power management circuit **46** if the temporarily stored DC voltage is greater than a predetermined voltage threshold.

In a more preferred form of the present invention, the energy harvesting device includes a solar cell circuit having a solar cell **40**. The solar cell circuit receives light energy and generates a solar cell DC output voltage in response thereto. The solar cell DC output voltage is provided to at least one of the main energy storage device **18**, the jump start DC voltage device **44** and the output connector **30**. Furthermore, a second power management circuit **48** may be included for the solar cell circuit. The second power management circuit **48** is responsive to the solar cell DC output voltage and generates a managed solar cell DC output voltage in response thereto. The managed solar cell DC output voltage is provided to at least one of the main energy storage device **18**, the jump start DC voltage device **44** and the output connector **30**.

It should be noted that at least some of the DC voltages generated by the multiplier and rectifier circuits **42** may be coupled to provide group DC voltages, and the group DC voltages may be combined in parallel to define the combined DC voltage provided to the temporary storage device **14**.

In a more specific form of the present invention, the plurality of antennas **2** of the energy harvesting device includes a first antenna **2***a*, a second antenna **2***b*, a third antenna **2***c* and a fourth antenna **2***d*, the first antenna **2***a* generating a first RF electrical signal, the second antenna **2***b* generating a second RF electrical signal, the third antenna **2***c* generating a third RF electrical signal, and the fourth antenna **2***d* generating a fourth RF electrical signal. Furthermore, the plurality of multiplier and rectifier circuits **42** of the energy harvesting device includes a first multiplier and rectifier circuit **42***a*, a second multiplier and rectifier circuit **42***b*, a third multiplier and rectifier circuit **42***c* and a fourth multiplier and rectifier circuit **42***d*, the first multiplier and rectifier circuit **42***a* being responsive to the first RF electrical signal generated by the first antenna **2***a* and generating a first multiplied and rectified DC voltage in response thereto, the second multiplier and rectifier circuit **42***b* being responsive to the second RF electrical signal generated by the second antenna **2***b* and generating a second multiplied and rectified DC voltage in response thereto, the third multiplier and rectifier circuit **42***c* being responsive to the third RF electrical signal generated by the third antenna **2***c* and generating a third multiplied and rectified DC voltage in response thereto, and the fourth multiplier and rectifier circuit **42***d* being responsive to the fourth RF electrical signal generated by the fourth antenna **2***d* and generating a fourth multiplied and rectified DC voltage in response thereto. The first multiplied and rectified DC voltage and the second multiplied and rectified DC voltage are preferably coupled in series to define a first group DC voltage. Similarly, the third multiplied and rectified DC voltage and the fourth multiplied and rectified DC voltage are preferably coupled in series to define a second group DC voltage. The first group DC voltage and the second group DC voltage are preferably combined in parallel to define the combined DC voltage which is provided to the temporary storage device **14**.

Each antenna **2** of the plurality of antennas may have either a broadband bandwidth characteristic or a narrowband bandwidth characteristic, or the antennas **2** may be a mix of broadband and narrowband bandwidth characteristics.

The energy harvesting device of the present invention preferably includes a housing **32**. The housing **32** has a base **36** defining an internal cavity for containing the electrical circuit of the energy harvesting device, and a cover **34** pivotally mounted on the base **36**. The base **36** has a top surface **38**, and the cover **34** is preferably pivotable between at least a closed position in which the cover **34** is in close proximity to the base **36** to at least partially cover the top surface **38**, and an open position in which the cover **34** is substantially perpendicular to the top surface **38** of the base.

The plurality of antennas **2** is preferably mounted on the pivotable cover **34** of the housing **32** and are positionable in at least a first position in which the plurality of antennas **2** is in close proximity to the top surface **38** of the base **36** when the cover **34** is in the closed position, and a second position in which the plurality of antennas **2** is in a raised position from the top surface **38** of the base **36** when the cover **34** is in the open position.

If a solar cell circuit is included in the energy harvesting device, where the solar cell circuit includes a solar cell **40** for receiving light energy, the solar cell **40** is preferably mounted on the top surface **38** of the base **36** and is selectively covered and uncovered by the cover **34** when the cover **34** is respectively pivoted between the closed position and the open position. The cover **34** is preferably at least partially translucent to at least partially allow light energy to pass therethrough and to be received by the solar cell **40** when the cover **34** is in the closed position.

Alternatively, the energy harvesting device includes a housing **32** having a top surface **38**, whereby the solar cell **40** is mounted on the top surface **38** of the housing. A cover need not be included. The housing **32** may include a base **36** defining an internal cavity for containing the electrical circuit of the energy harvesting device, the top surface **38** of the housing forming a portion of the base **36**. Additionally, a non-pivotable cover **34** may be mounted on the base **36**, the cover **34** at least partially covering the top surface **38** of the base **36** and the solar cell **40** mounted on the top surface **38**. In this embodiment, it is preferred if the cover **34** is at least partially translucent to allow light energy to pass therethrough and impinge on the solar cell **40** situated below the cover **34**.

Now, various forms of a method of harvesting energy in accordance with the present invention will further be described in detail.

In one form of the present invention, a method of harvesting energy includes the steps of receiving a transmitted radio frequency (RF) signal to provide a received RF signal, converting the received RF signal to an RF electrical signal, converting the RF electrical signal to a direct current (DC) voltage, temporarily storing the DC voltage to provide a temporarily stored DC voltage, monitoring the temporarily stored DC voltage and generating a pulsed output signal if the temporarily stored DC voltage is above a first predetermined voltage level, converting the temporarily stored DC voltage to a first converted DC voltage which is greater than the temporarily stored DC voltage, converting the first converted DC voltage to a second converted DC voltage which is less than the first converted DC voltage, storing the second converted DC voltage to provide a stored second converted DC voltage, converting the stored second converted DC voltage to a third converted DC voltage which is greater than the stored second converted DC voltage, and providing the third converted DC voltage to an output connector **30**, an electronic device **8** being connectable to the output connector **30** for receiving thereon the third converted DC voltage provided to the output connector **30**.

The method of harvesting energy described above may further include the step of connecting a source of external DC voltage to an input connector **24**, the input connector **24** receiving the external DC voltage, the first converted DC voltage being at least partially defined by the external DC voltage.

Furthermore, the method of harvesting energy described above may further include the step of monitoring the stored second converted DC voltage and not generating the pulsed output signal if the stored second converted DC voltage is above a second predetermined voltage level.

In another form of the present invention, a method of harvesting energy includes the steps of receiving a transmitted radio frequency (RF) signal to provide a received RF signal, converting the received RF signal to a direct current (DC) voltage, and providing the DC voltage on an output connector **30**, an electronic device **8** being connectable to the output connector **30** for receiving the DC voltage provided on the output connector **30**.

In yet another form of the present invention, a method of harvesting energy includes the steps of receiving by a plurality of antennas **2** a transmitted radio frequency (RF) signal and generating RF electrical signals in response to the transmitted RF signals received by the plurality of antennas **2**, multiplying and rectifying the RF electrical signals generated by the plurality of antennas **2** and generating a plurality of direct current (DC) voltages in response thereto, combining in series at least some of the DC voltages to provide a combined DC voltage, the combined DC voltage being greater in magnitude than each individual DC voltage, temporarily storing the combined DC voltage thereby providing a temporarily stored DC voltage, generating a DC charging voltage in response to the temporarily stored DC voltage, storing the DC charging voltage to provide a stored DC charging voltage, and generating a DC output connector voltage on an output connector **30** in response to the stored DC charging voltage, an electronic device **8** being connectable to the output connector **30** for receiving thereon the output connector DC voltage provided on the output connector **30**.

Furthermore, the method of harvesting energy described above may further include the step of generating a jump start DC voltage, the combined DC voltage including the at least some of the DC voltages generated by the multiplying and rectifying step connected in series and the jump start DC voltage, and may further include the step of connecting an external DC voltage to an input connector **24**, at least one of the stored DC charging voltage, the jump start DC voltage and the output connector DC voltage being defined at least partially by the external DC voltage.

Additionally, the method of harvesting energy described previously may include the step of converting the stored DC charging voltage to the output connector DC voltage provided on the output connector **30**, and may include the further step of monitoring the temporarily stored DC voltage and selectively generating the DC charging voltage if the temporarily stored DC voltage is greater than a predetermined voltage threshold.

If a solar cell circuit is included in the energy harvesting device of the present invention, then the method of harvesting energy described above may include the step of receiving light energy by the solar cell circuit and generating a solar cell DC output voltage in response thereto, the at least one of the stored DC charging voltage, the output connector DC voltage provided on the output connector and the jump start DC voltage being defined at least partially by the solar cell DC output voltage.

The method of harvesting energy may further include the steps of coupling in series at least some of the DC voltages generated by the multiplying and rectifying step to provide group DC voltages, and combining the group DC voltages in parallel to define the combined DC voltage.

The method of harvesting energy may further include the step of adjustably positioning the plurality of antennas **2** between a first position and a second position, wherein the plurality of antennas **2** exhibits better signal reception characteristics to receive a transmitted RF signal when in the first position than when in the second position.

Although illustrative embodiments of the present invention have been described herein with reference to the accompanying drawings, it is to be understood that the invention is not limited to those precise embodiments, and that various other changes and modifications may be effected therein by one skilled in the art without departing from the scope or spirit of the invention.

What is claimed is:

1. An energy harvesting device, which comprises:

at least one antenna for receiving a transmitted radio frequency (RF) signal, the at least one antenna converting the received RF signal to an RF electrical signal;

at least one RF-to-DC rectifier circuit, the at least one RF-to-DC rectifier circuit being operatively connected to the at least one antenna and converting the RF electrical signal to a direct current (DC) voltage;

a first storage device, the first storage device being operatively connected to the at least one RF-to-DC rectifier circuit and being provided with the DC voltage and being charged thereby;

a microcontroller, the microcontroller having a first signal input operatively connected to the first storage device to monitor the DC voltage on the first storage device, the microcontroller generating a pulsed output signal if the DC voltage on the first storage device is above a first pre-determined voltage level;

a first stage DC-to-DC voltage converter circuit, the first stage DC-to-DC voltage converter circuit being operatively connected to the first storage device and generating an output DC voltage which is greater than the DC voltage on the first storage device;

a second stage DC-to-DC voltage converter circuit, the second stage DC-to-DC voltage converter circuit being operatively connected to the first stage DC-to-DC voltage converter circuit and generating an output DC voltage which is less than the output DC voltage generated by the first stage DC-to-DC voltage converter circuit;

a second storage device, the second storage device being operatively connected to the second stage DC-to-DC voltage converter circuit and being provided with the output DC voltage generated by the second stage DC-to-DC voltage converter circuit and being charged thereby;

a third stage DC-to-DC voltage converter circuit, the third stage DC-to-DC voltage converter circuit being operatively connected to the second storage device and generating an output DC voltage which is greater than the DC voltage on the second storage device; and

an output connector, the output connector being operatively connected to the third stage DC-to-DC voltage converter circuit and providing the output DC voltage generated by the third stage DC-to-DC voltage converter circuit thereon, an electronic device being connectable to the output connector for receiving thereon the output DC voltage provided to the output connector.

2. An energy harvesting device as defined by claim **1**, which further comprises:

an input connector, the input connector being operatively connected to the second stage DC-to-DC voltage converter circuit, the input connector being connectable to an external source of DC voltage for providing the DC voltage from the external source to the second stage DC-to-DC voltage converter circuit, the second stage DC-to-DC voltage converter circuit generating the output DC voltage of the second stage DC-to-DC voltage converter circuit in response to the DC voltage from the external source provided on the input connector.

3. An energy harvesting device as defined by claim **1**, wherein the first storage device includes a capacitor.

4. An energy harvesting device as defined by claim **1**, wherein the second storage device includes a battery.

5. An energy harvesting device as defined by claim **1**, wherein the microcontroller includes a second signal input operatively connected to the second storage device to monitor the DC voltage on the second storage device, the microcontroller not generating the pulsed output signal if the DC voltage on the second storage device is above a second predetermined voltage level.

6. An energy harvesting device as defined by claim **1**, which further comprises:

an input connector, the input connector being connectable to a source of DC voltage external to the energy harvesting device, the DC voltage of the external source being provided to at least one of the second storage device and the output connector.

7. An energy harvesting device as defined by claim **1**, which further comprises:

a solar cell circuit, the solar cell circuit receiving light energy and generating a solar cell DC output voltage in response thereto, the solar cell DC output voltage being provided to at least one of the second storage device and the output connector.

8. An energy harvesting device as defined by claim **1**, wherein the at least one antenna includes a plurality of antennas.

9. An energy harvesting device as defined by claim **8**, wherein each antenna of the plurality of antennas has a broadband bandwidth characteristic.

10. An energy harvesting device as defined by claim **8**, wherein each antenna of the plurality of antennas has a narrowband bandwidth characteristic.

11. An energy harvesting device as defined by claim **1**, which further comprises:

a housing, the housing having a base defining an internal cavity, and a cover pivotally mounted on the base, the base having a top surface, the cover being pivotable between at least a closed position in which the cover is in close proximity to the base to at least partially cover the top surface, and an open position in which the cover is substantially perpendicular to the top surface of the base.

12. An energy harvesting device as defined by claim **11**, wherein the at least one antenna is mounted on the pivotable cover of the housing and being positionable in at least a first position in which the at least one antenna is in close proximity to the top surface of the base when the cover is in the closed position, and a second position in which the at least one antenna is in a raised position from the top surface of the base when the cover is in the open position.

13. An energy harvesting device as defined by claim **11**, which further comprises:

a solar cell circuit, the solar cell circuit including a solar cell for receiving light energy, the solar cell circuit generating a solar cell DC output voltage in response to the light energy received by the solar cell, the solar cell being mounted on the top surface of the base and selectively covered and uncovered by the cover when the cover is respectively pivoted between the closed position and the open position.

14. An energy harvesting device as defined by claim **1**, which further comprises:

a solar cell circuit, the solar cell circuit including a solar cell for receiving light energy, the solar cell circuit generating a solar cell DC output voltage in response to the light energy received by the solar cell; and

a housing, the housing having a top surface, the solar cell being mounted on the top surface of the housing.

15. An energy harvesting device as defined by claim **14**, wherein the housing includes a base defining an internal cavity, and a cover mounted on the base, the top surface of the housing forming a portion of the base, the cover at least partially covering the top surface of the base and the solar cell mounted on the top surface.

16. An energy harvesting device as defined by claim **15**, wherein the cover is at least partially translucent to at least partially allow light energy to pass therethrough and to be received by the solar cell.

17. An energy harvesting device as defined by claim **12**, wherein the cover is at least partially translucent to at least partially allow light energy to pass therethrough and to be received by the solar cell when the cover is in the closed position.

18. An energy harvesting device, which comprises:

a plurality of antennas for receiving a transmitted radio frequency (RF) signal, the antennas generating RF electrical signals in response to the transmitted RF signals received thereby;

a plurality of multiplier and rectifier circuits, each multiplier and rectifier circuit being responsive to a respective RF electrical signal generated by an antenna of the plurality of antennas and generating a direct current (DC) voltage in response thereto, at least some of the DC voltages being stacked in series to provide a combined DC voltage, the combined DC voltage being greater in magnitude than each individual DC voltage generated by a respective multiplier and rectifier circuit;

a temporary storage device, the temporary storage device being responsive to the combined DC voltage and providing a temporarily stored DC voltage in response thereto;

a first power management circuit, the first power management circuit being responsive to the temporarily stored DC voltage and generating a DC charging voltage in response thereto;

a main energy storage device, the main energy storage device being responsive to the DC charging voltage generated by the first power management circuit and providing a main energy storage DC voltage in response thereto; and

an output connector, the output connector providing an output connector DC voltage thereon in response to the main energy storage DC voltage, an electronic device being connectable to the output connector for receiving thereon the output connector DC voltage provided on the output connector,

wherein at least some of the DC voltages generated by the multiplier and rectifier circuits are coupled in series to provide group DC voltages, and wherein the group DC voltages are combined in parallel to define the combined DC voltage;

wherein the plurality of antennas includes a first antenna, a second antenna, a third antenna and a fourth antenna, the first antenna generating a first RF electrical signal, the second antenna generating a second RF electrical signal, the third antenna generating a third RF electrical signal, the fourth antenna generating a fourth RF electrical signal;

wherein the plurality of multiplier and rectifier circuits includes a first multiplier and rectifier circuit, a second multiplier and rectifier circuit, a third multiplier and rectifier circuit and a fourth multiplier and rectifier circuit, the first multiplier and rectifier circuit being responsive to the first RF electrical signal generated by the first antenna and generating a first multiplied and rectified DC voltage in response thereto, the second multiplier and rectifier circuit being responsive to the second RF electrical signal generated by the second antenna and generating a second multiplied and rectified DC voltage in response thereto, the third multiplier and rectifier circuit being responsive to the third RF electrical signal generated by the third antenna and generating a third multiplied and rectified DC voltage in response thereto, the fourth multiplier and rectifier circuit being responsive to the fourth RF electrical signal generated by the fourth antenna and generating a fourth multiplied and rectified DC voltage in response thereto;

wherein the first multiplied and rectified DC voltage and the second multiplied and rectified DC voltage are coupled in series to define a first group DC voltage;

wherein the third multiplied and rectified DC voltage and the fourth multiplied and rectified DC voltage are coupled in series to define a second group DC voltage;

and wherein the first group DC voltage and the second group DC voltage are combined in parallel to define the combined DC voltage.

19. An energy harvesting device as defined by claim **18**, which further comprises:

a jump start DC voltage device, the jump start DC voltage device providing a jump start DC voltage, the combined DC voltage including the at least some of the DC voltages generated by the plurality of multiplier and rectifier circuits stacked in series and the jump start DC voltage.

20. An energy harvesting device as defined by claim **18**, which further comprises:

an input connector, the input connector being connectable to a source of DC voltage external to the energy harvesting device, the DC voltage of the external source being provided to at least one of the main energy storage device and the output connector.

21. An energy harvesting device as defined by claim **18**, which further comprises:

a DC-to-DC voltage converter circuit, the DC-to-DC voltage converter circuit being responsive to the main energy storage DC voltage and generating an output DC voltage in response thereto, the output connector providing the output connector DC voltage in response to the output DC voltage generated by the DC-to-DC voltage converter circuit.

22. An energy harvesting device as defined by claim **18**, which further comprises:

a watchdog monitor circuit, the watchdog monitor circuit being responsive to the temporarily stored DC voltage and selectively providing the temporarily stored DC voltage to the first power management circuit if the temporarily stored DC voltage is greater than a predetermined voltage threshold.

23. An energy harvesting device as defined by claim **18**, which further comprises:

a solar cell circuit, the solar cell circuit receiving light energy and generating a solar cell DC output voltage in response thereto, the solar cell DC output voltage being provided to at least one of the main energy storage device and the output connector.

24. An energy harvesting device as defined by claim **19**, which further comprises:

a solar cell circuit, the solar cell circuit receiving light energy and generating a solar cell DC output voltage in response thereto, the solar cell DC output voltage being provided to at least one of the main energy storage device, the output connector and the jump start DC voltage device.

25. An energy harvesting device as defined by claim **18**, which further comprises:

a solar cell circuit, the solar cell circuit receiving light energy and generating a solar cell DC output voltage in response thereto; and

a second power management circuit, the second power management circuit being responsive to the solar cell DC output voltage and generating a managed solar cell DC output voltage in response thereto, the managed solar cell DC output voltage being provided to at least one of the main energy storage device and the output connector.

26. An energy harvesting device as defined by claim **19**, which further comprises:

a solar cell circuit, the solar cell circuit receiving light energy and generating a solar cell DC output voltage in response thereto; and

a second power management circuit, the second power management circuit being responsive to the solar cell DC output voltage and generating a managed solar cell DC output voltage in response thereto, the managed solar cell DC output voltage being provided to at least one of the main energy storage device, the output connector and the jump start DC voltage device.

27. An energy harvesting device as defined by claim **18**, wherein each antenna of the plurality of antennas has a broadband bandwidth characteristic.

28. An energy harvesting device as defined by claim **18**, wherein each antenna of the plurality of antennas has a narrowband bandwidth characteristic.

29. An energy harvesting device as defined by claim **18**, which further comprises:

a housing, the housing having a base defining an internal cavity, and a cover pivotally mounted on the base, the base having a top surface, the cover being pivotable between at least a closed position in which the cover is in close proximity to the base to at least partially cover the top surface, and an open position in which the cover is substantially perpendicular to the top surface of the base.

30. An energy harvesting device as defined by claim **29**, wherein the plurality of antennas is mounted on the pivotable cover of the housing and being positionable in at least a first position in which the plurality of antennas is in close proximity to the top surface of the base when the cover is in the closed position, and a second position in which the plurality of antennas is in a raised position from the top surface of the base when the cover is in the open position.

31. An energy harvesting device as defined by claim **29**, which further comprises:

a solar cell circuit, the solar cell circuit including a solar cell for receiving light energy, the solar cell circuit generating a solar cell DC output voltage in response to the light energy received by the solar cell, the solar cell being mounted on the top surface of the base and selectively covered and uncovered by the cover when the cover is respectively pivoted between the closed position and the open position.

32. An energy harvesting device as defined by claim **18**, which further comprises:

a solar cell circuit, the solar cell circuit including a solar cell for receiving light energy, the solar cell circuit generating a solar cell DC output voltage in response to the light energy received by the solar cell; and

a housing, the housing having a top surface, the solar cell being mounted on the top surface of the housing.

33. An energy harvesting device as defined by claim **32**, wherein the housing includes a base defining an internal cavity, and a cover mounted on the base, the top surface of the housing forming a portion of the base, the cover at least partially covering the top surface of the base and the solar cell mounted on the top surface.

34. An energy harvesting device as defined by claim **33**, wherein the cover is at least partially translucent to at least partially allow light energy to pass therethrough and to be received by the solar cell.

35. An energy harvesting device as defined by claim **30**, wherein the cover is at least partially translucent to at least partially allow light energy to pass therethrough and to be received by the solar cell when the cover is in the closed position.

36. An energy harvesting device as defined by claim **18**, wherein the temporary storage device includes a capacitor.

37. An energy harvesting device as defined by claim **18**, wherein the main energy storage device includes a battery.

38. An energy harvesting device as defined by claim **19**, wherein the jump start DC voltage device includes a battery.

39. A method of harvesting energy, which comprises the steps of:

receiving a transmitted radio frequency (RF) signal to provide a received RF signal;

converting the received RF signal to an RF electrical signal;

converting the RF electrical signal to a direct current (DC) voltage;

temporarily storing the DC voltage to provide a temporarily stored DC voltage;

monitoring the temporarily stored DC voltage and generating a pulsed output signal if the temporarily stored DC voltage is above a first predetermined voltage level;

converting the temporarily stored DC voltage to a first converted DC voltage which is greater than the temporarily stored DC voltage;

converting the first converted DC voltage to a second converted DC voltage which is less than the first converted DC voltage;

storing the second converted DC voltage to provide a stored second converted DC voltage;

converting the stored second converted DC voltage to a third converted DC voltage which is greater than the stored second converted DC voltage; and

providing the third converted DC voltage to an output connector, an electronic device being connectable to the output connector for receiving thereon the third converted DC voltage provided to the output connector.

40. A method of harvesting energy as defined by claim **39**, which further comprises the step of:

connecting a source of external DC voltage to an input connector, the input connector receiving the external DC voltage, the first converted DC voltage being at least partially defined by the external DC voltage.

41. A method of harvesting energy as defined by claim **39**, wherein the step of temporarily storing the DC voltage is at least partially performed by using a capacitor.

42. A method of harvesting energy as defined by claim **39**, wherein the step of storing the second converted DC voltage is at least partially performed by using a battery.

43. A method of harvesting energy as defined by claim **39**, which further comprises the step of:

monitoring the stored second converted DC voltage and not generating the pulsed output signal if the stored second converted DC voltage is above a second predetermined voltage level.

44. A method of harvesting energy, which comprises the steps of:

receiving by a plurality of antennas a transmitted radio frequency (RF) signal and generating RF electrical signals in response to the transmitted RF signals received by the plurality of antennas;

multiplying and rectifying the RF electrical signals generated by the plurality of antennas and generating a plurality of direct current (DC) voltages in response thereto;

combining in series at least some of the DC voltages to provide a combined DC voltage, the combined DC voltage being greater in magnitude than each individual DC voltage;

temporarily storing the combined DC voltage thereby providing a temporarily stored DC voltage;

monitoring the temporarily stored DC voltage and generating a pulsed output signal if the temporarily stored DC voltage is above a first predetermined voltage level;

converting the temporarily stored DC voltage to a first converted DC voltage which is greater than the temporarily stored DC voltage;

converting the first converted DC voltage to a second converted DC voltage which is less than the first converted DC voltage;

storing the second converted DC voltage to provide a stored second converted DC voltage;

converting the stored second converted DC voltage to a third converted DC voltage which is greater than the stored second converted DC voltage; and

providing the third converted DC voltage to an output connector, an electronic device being connectable to the output connector for receiving thereon the third converted DC voltage provided to the output connector.

45. A method of harvesting energy as defined by claim **44**, which further comprises the step of:

generating a jump start DC voltage, the combined DC voltage including the at least some of the DC voltages generated by the multiplying and rectifying step connected in series and the jump start DC voltage.

46. A method of harvesting energy as defined by claim **44**, which further comprises the step of:

connecting an external DC voltage to an input connector, at least one of the stored DC charging voltage and the output connector DC voltage being defined at least partially by the external DC voltage.

47. A method of harvesting energy as defined by claim **44**, which further comprises the step of:

converting the stored DC charging voltage to the output connector DC voltage provided on the output connector.

48. A method of harvesting energy as defined by claim **44**, which further comprises the step of:

monitoring the temporarily stored DC voltage and selectively generating the DC charging voltage if the temporarily stored DC voltage is greater than a predetermined voltage threshold.

49. A method of harvesting energy as defined by claim **44**, which further comprises the step of:

receiving light energy by a solar cell circuit and generating a solar cell DC output voltage in response thereto, at least one of the stored DC charging voltage and the output connector DC voltage provided on the output connector being defined at least partially by the solar cell DC output voltage.

50. A method of harvesting energy as defined by claim **45**, which further comprises the step of:

receiving light energy by a solar cell circuit and generating a solar cell DC output voltage in response thereto, the at least one of the stored DC charging voltage, the output connector DC voltage provided on the output connector and the jump start DC voltage being defined at least partially by the solar cell DC output voltage.

51. A method of harvesting energy as defined by claim **44**, which further comprises the steps of:

coupling in series at least some of the DC voltages generated by the multiplying and rectifying step to provide group DC voltages; and

combining the group DC voltages in parallel to define the combined DC voltage.

52. A method of harvesting energy as defined by claim **44**, wherein each antenna of the plurality of antennas has a broadband bandwidth characteristic.

53. A method of harvesting energy as defined by claim **44**, wherein each antenna of the plurality of antennas has a narrowband bandwidth characteristic.

54. A method of harvesting energy as defined by claim **44**, which further comprises the steps of:

adjustably positioning the plurality of antennas between a first position and a second position, wherein the plurality of antennas exhibits better signal reception characteristics to receive a transmitted RF signal when in the first position than when in the second position.

55. A method of harvesting energy as defined by claim **49**, which further comprises the step of:

mounting the plurality of antennas and at least a portion of the solar cell circuit to a housing, the housing having a base defining an internal cavity, and a cover pivotally mounted on the base, the base having a top surface, the cover being pivotable between at least a closed position in which the cover is in close proximity to the base to at least partially cover the top surface, and an open position in which the cover is substantially perpendicular to the top surface of the base, the plurality of antennas being mounted on the pivotable cover of the housing and being positionable in at least a first position in which the plurality of antennas is in close proximity to the top surface of the base when the cover is in the closed position, and a second position in which the plurality of antennas is in a raised position from the top surface of the base when the cover is in the open position, the at least portion of the solar cell circuit being mounted on the top surface of the base and selectively covered and uncovered by the cover when the cover is respectively pivoted between the closed position and the open position.

56. A method of harvesting energy as defined by claim **55**, wherein the cover is at least partially translucent to at least partially allow light energy to pass therethrough and to be received by the at least portion of the solar cell circuit.

57. A method of harvesting energy as defined by claim **44**, wherein the step of temporarily storing the combined DC voltage is at least partially performed by using a capacitor.

58. A method of harvesting energy as defined by claim **44**, wherein the step of storing the DC charging voltage is at least partially performed by using a battery.

59. A method of harvesting energy as defined by claim **45**, wherein the step of generating a jump start DC voltage is at least partially performed by using a battery.

(57) **ABSTRACT**

An antenna device for transmitting and/or receiving electromagnetic radiation, installable in and connectable to a communication device, inlcudes an antenna structure switchable between a plurality of antenna configuration states. Each antenna configuration state is distinguished by a set of radiation parameters, such as resonance frequency, input impedance, bandwidth, radiation pattern, gain, polarization, and near-field pattern. Each of the plurality of antenna configuration states is adapted for use of the antenna device in the communication device in a respective predefined physical operation environment. A switching device selectively switches the antenna structure between the plurality of antenna configuration states.

ANTENNA DEVICE FOR TRANSMITTING AND/OR RECEIVING RADIO FREQUENCY WAVES AND METHOD RELATED THERETO

CROSS REFERENCE TO RELATED APPLICATIONS

The present invention claims priority to commonly assigned Swedish Patent Application Serial No. 9903945-5 filed Oct. 29, 1999 and is a continuation of PCT Patent Application Serial No. PCT/SE00/02059 filed on Oct. 24, 2000, the entire contents of all of which are hereby incorporated by reference in their entirety for all purposes. The present application is also related to commonly assigned, co-pending U.S. patent application Ser. No. 09/712,131 entitled "An antenna device for transmitting and/or receiving RF waves", now U.S. Pat. No. 6,392,610; U.S. patent application Ser. No. 09/712,181 entitled "Antenna device and method for transmitting and receiving radio waves"; and U.S. patent application Ser. No. 09/712,133 entitled "Antenna device and method for transmitting and receiving radio frequency waves", all of which were filed concurrently herewith. These applications are based on the following corresponding PCT applications: PCT/SE00/02058; PCT/SE00/02056; and PCT/SE00/02057, respectively, all filed on Oct. 24, 2000, the entire contents of which are hereby incorporated by reference in their entirety for all purposes.

TECHNICAL FIELD OF THE INVENTION

The present invention relates generally to an antenna device, a radio communication device including the antenna device, and a method for transmitting and receiving electromagnetic waves. More particularly, the present invention is related to an antenna device that is adaptable to a variety of conditions.

BACKGROUND OF THE INVENTION

In modern communication systems, there is an ever-increasing demand for smaller and more versatile portable wireless terminals, e.g., hand-portable telephones. It is well known that the size of an antenna is a critical factor for its performance. Further, the interaction between the antenna, the telephone body and the close-by environment, such as the user, will become more important as the wireless terminals become smaller and smaller. It is thus a formidable task to manufacture such compact and versatile terminals, which exhibit good antenna performance under a variety of conditions.

In current manufacturing of hand-portable telephones, the antenna is commonly adapted to the characteristics of the specific telephone and to be suited for a default use in a default environment. This means that the antenna cannot later on be adapted to any specific condition under which a certain telephone is to be used.

The radiating properties of an antenna device for a portable telephone depends heavily on the shape and size of the support structure such as a printed circuit board (PCB) of the telephone and of the telephone casing. All radiation properties, such as resonance frequency, radiation pattern, polarization, impedance and bandwidth are a product of the antenna device itself and its interaction with the PCB and the telephone casing. Thus, all references to radiation properties made below are intended to be for the whole device in which the antenna is incorporated.

What has been stated above is true also with respect to other communication devices, such as cordless telephones, telemetry systems, wireless data terminals, etc. Thus, the antenna device of the invention is applicable on a broad scale in various communication devices.

SUMMARY OF THE INVENTION

The present invention is therefore directed to an antenna device, a communication device including the antenna device and a method of receiving and transmitting electromagnetic waves that substantially overcomes one or more of the problems due to the limitations and disadvantages noted above.

It is an object of the present invention is to provide a versatile antenna device, adaptable to various conditions, for a communication device. In this respect, it is a particular object of the invention to provide a versatile antenna device, which is adaptable to its close-by environment.

It is yet a further object of the invention to provide an antenna device of which certain characteristics, such as resonance frequency, input impedance bandwidth, radiation pattern, gain, is polarization, and near-field pattern, are easily controllable.

It is still a further object to provide an antenna device that is simple, lightweight, easy to manufacture and inexpensive.

It is yet a further object to provide an antenna device which is efficient, easy to install and reliable, particularly mechanically durable, even after long use.

It is still a further object of the invention to provide an antenna device suited to be used as an integrated part of a communication device.

These and other objects of the present invention will become more readily apparent from the detailed description given hereinafter. However, it should be understood that the detailed description and specific examples, while indicating the preferred embodiments of the invention, are given by way of illustration only, since various changes and modifications within the spirit and scope of the invention will become apparent to those skilled in the art from this detailed description.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention will become more fully understood from the detailed description of embodiments of the present invention given hereinbelow and the accompanying FIGS. **1–9**, which are given by way of illustration only, and thus are not limitative of the invention.

FIG. **1** is a perspective view of two casing parts of a portable telephone including one embodiment of an antenna device according to the present invention.

FIGS. **2–8** schematically illustrate additional embodiments of an antenna device according to the invention.

FIG. **9** is a flow diagram of an example of a switch-and-stay algorithm for controlling a switching device of an inventive antenna device.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

In the following description, for purposes of explanation and not limitation, specific details are set fourth in order to provide a thorough understanding of the present invention. However, it will be apparent to one skilled in the art that the present invention may be practiced in other embodiments that depart from these specific details. In other instances, detailed descriptions of well-known devices and methods are omitted so as not to obscure the description of the present invention with unnecessary details.

In this disclosure it is to be understood that the antenna system of the invention is operable to transmit or receive electromagnetic signals. Even if a term is used herein that suggests one specific signal direction it is to be appreciated that such a situation can cover that signal direction and/or its reverse. The expression "antenna structure" is intended to include active elements connected to the transmission (feed) line(s) of the communication device circuitry, as well as elements that can be grounded or left disconnected, and hence operate as, e.g., directors, reflectors, impedance matching elements.

According to the present invention, there is provided an antenna device for transmitting and/or receiving RF radiation, which is installable in and connectable to a radio communication device. The antenna device includes an antenna structure, which is switchable between a plurality of antenna configuration states. Each antenna configuration is distinguished by a set of radiation parameters, such as resonance frequency, input impedance, bandwidth, radiation pattern, gain, polarization, and near-field pattern. The antenna device also includes a switching device for selectively switching the antenna structure between the plurality of antenna configuration states.

In the antenna device, each of the antenna configuration states is adapted for use of the antenna device in the radio communication device in a respective predefined physical operation environment. These predefined physical operation environments may include a talk position (TP), a free space position (FS), a waist position (WP) and a pocket position (PP). A predefined physical operation environment as used herein preferably means a close-by environment, which includes objects that affect the above-mentioned parameters of the antenna structure, particularly when being installed in a small-sized radio communication device. Close-by operation environment as used herein preferably means any object at a distance from the radio communication device within which the effect on the antenna parameters is noticeable. This distance may extend ten wavelengths from the device, but optionally it may extend five wavelengths, a few wavelengths, or only roughly about one wavelength from the device. The environment includes, of course, the user of the communication device.

Furthermore, the present invention includes various approaches for sensing the physical operation environment and various procedures for controlling the switching of the antenna device.

The description is hereinbelow divided into five main sections covering various aspects of the present invention. The first section gives an overview of a manifold of different antenna structures and switching devices that may be employed in the present invention. Thereafter, a description of different physical operation environments is given. A discussion about radiation related parameters that may be affected by the different operation environments follows, and which parameter changes may be compensated for by switching to another antenna configuration state. The discussion focuses primarily on the parameters resonance frequency, impedance and radiation pattern and two specific examples are briefly overviewed. Subsequently, some approaches for sensing the physical operation environment are depicted, and, finally some procedures for controlling the switching of the antenna device are outlined.

Antenna Structures and Switching Devices

In FIG. **1** a front part **20** and the back part **21** of the casing of a portable telephone are shown. The main printed circuit board (PCB) of the phone is to be mounted in the space **1** in the front part **20** of the casing. An antenna device **2** of the present invention is printed on a separate supporting device **22** in this embodiment. The support can be a flexible substrate, a Molded Interconnection Device (MID) or a PCB. However, the antenna could have been printed on the main PCB, as well, which can extend along the length of the bottom casing. There are RF feed lines and control lines for the switching device between the phone circuit on the PCB and the antenna device.

The antenna device **2** includes a switching device **4**. The switching device **4** includes a matrix of electrically controllable switching elements. The switching elements can include microelectro-mechanical system switches (MEMS), PIN diode switches, or GaAs field effect transistors (FET).

The switching device **4** is surrounded by an antenna structure including a pattern of antenna elements. Each antenna element is connected to a respective switch in the switching device arranged for connecting and disconnecting the antenna element. In this embodiment, the radiating structure includes four loop-shaped antenna elements **5**. A loop-shaped parasitic element **6** is formed within each of the loop-shaped antenna elements **5**. A meander-shaped antenna element **7** is arranged between each pair of loop-shaped elements **5**, **6**. The antenna elements form a symmetrical pattern around the switching device **4**. However, in certain applications the antenna elements can form an unsymmetrical pattern. Further, the radiation structure can include additional antenna elements not connected to the switching device.

The switching device **4** allows the antenna structure **2** to be selectively switchable between a number of antenna configuration states, each of which is distinguished by a set of radiation parameters, such as resonance frequency, input impedance, bandwidth, radiation pattern, gain, polarization and near-field pattern. The various antenna configuration states may be obtained by connecting loop-shaped antenna elements in parallel or in series with each other, or some elements can be connected in series and some in parallel. Further, one or more elements can be completely disconnected or connected to a RF ground plane. One or more of the meander-shaped antenna elements **7** can be used separately or in any combination with the loop antenna elements. The meander-shaped antenna elements **7** can also be segmented so that only one or more selected portions thereof can be connected if desired.

Although not illustrated in FIG. **1**, other types of antenna elements, such as patch antennas, slot antennas, whip antennas, helical antennas, zigzag antennas and fractal antennas can also be used. In all cases, the switching device **4** may or may not be surrounded by the antenna elements and the antenna elements can also be positioned on one side of the switching device.

All switching of the antenna elements is centralized to the switching device **4**, which can be very small with a controllable interaction with the antenna function. Further, as all switching is centralized to the switching device **4**, switch control signals need only be supplied to the switching device **4**, thereby simplifying the overall antenna structure, as well as providing other advantages.

The connection/disconnection of the antenna elements are easily controllable by the switching device **4**. By appropriate selection of the combination of antenna elements that are connected to the RF feed, i.e., the antenna configuration state, the impedance and/or the resonance frequency of the antenna device can be adjusted without the need for separate connection or disconnection of discrete components. The same effect can be achieved by using parasitic elements, not connected to RF feed, but connected to RF ground or unconnected. The parasitic elements can also be connected to the switching device. If the to use of discrete components in any application is desired, these discrete components can be easily connected or disconnected by use of the same switching device **4** as the other antenna elements.

Further, the radiation pattern of the antenna can be shaped according to demand by appropriate selection of antenna elements. In this way the influence due to objects in the close-by environment of the antenna device, such as the user of a portable phone, can be minimized among other things. It will also be possible to control the tuning, polarization, bandwidth, resonance frequency, gain, input impedance of the antenna device. These above depicted radiation related parameters will be discussed in more detail further below.

Next, a few more antenna configurations will briefly be discussed with reference to FIGS. **2**–**6**.

FIG. **2** is an example of an antenna device including a plurality of loop antenna elements **5**, **6** as in FIG. **1**. The loop antenna elements are arranged so that they start and end at the switching device **4**. The switching device **4** can be used to connect the loop antenna elements to a RF feed line, short-circuited, coupled in series or in parallel with each other. Each loop antenna element can therefore be seen as a portion of the total antenna structure, from now on called "the total antenna", having properties determined by the state of the switching device **4**. That is, the switching device **4** decides how the loop element portions are connected and electrically arranged. At least some of the loop antenna elements **5** can act as an actively radiating element, where the excitation is achieved through direct connection to a RF feed, preferably via a waveguide. Possibly, some of the loop antenna elements **6** can act as parasitic elements, where the excitation of the elements is achieved through parasitic coupling to other antenna elements.

The loop antenna elements can be shaped as three-dimensional structures. Parts or all of the structure can be positioned above the PCB. The pattern can go around, or through the PCB, so that part of the pattern is on the other side of the PCB. Some or all parts of the pattern can extend perpendicular to the PCB. There can be permanent shorting pins and/or components attached to the antenna elements outside of the switching device. The feeding of the antenna elements can also take place outside of the switching device.

The purpose of changing the antenna configuration state can be to match the antenna to a desired impedance. This can be done by switching in/out parasitic elements. The mutual coupling between the elements contributes to the input impedance of the active element, changing the resulting input impedance in a desired manner. Another purpose for altering the antenna configuration is to change the radiation pattern of the total antenna. This can be done by altering the connection of antenna portions so that the radiating currents are altered. This can also be done by switching in/out parasitic elements, thereby directing or reflecting the radiation towards a desired direction.

FIG. **3** shows an example of the antenna device where two meandering antenna elements **7** are connected to the central switching device **4**. The expression "meandering" element is intended also to cover other elements with similar shape and function, such as zigzag shape, snake shape, fractal shape, etc. What has been stated above in connection with the loop antenna elements **5**, **6** in FIG. **2** is applicable also regarding the meander shaped elements of FIG. **3**, as is realized by the person skilled in this art. The only difference between the configurations is the inherent difference in radiation characteristics between these two types of antenna elements as is well known in the art.

In FIG. **3**, connection lines **8**, which provide the RF feed and/or RF ground points of the meander antenna element **7**, can be switched between different positions along the meander antenna element **7**. The aim of this can be to change the input impedance for matching purposes or to change the current flow for radiation pattern control.

FIG. **4** shows an example of an antenna device where slot antenna elements **9** are connected to the central switching device **4**. The slot antenna elements **9** are connected to the switching device **4** via connection lines **10**. The connection lines **10** can be connected directly to a RF feed device, shorted, coupled in series or in parallel with lines to other antenna elements. Each connection line **10** can act as an active feed line and be connected directly to a RF feed device. Parasitic coupling, where there is no direct connection to any RF feed, can also be used.

At least one slot element **9** of the antenna device is fed by at least one connection line **10**, and in various ways tuned by the other lines. For example, the other lines can be shorted or left open so that the slot antenna element **9**, and, in effect, the whole antenna device, is tuned for a desired frequency band. The same technique can be used to change the radiation pattern of the wireless terminal, to which the antenna device is coupled, pattern shaping. Moreover, connecting, disconnecting or tuning other slot elements can provide tuning or pattern shaping.

FIG. **5** shows an example of an antenna device similar to that of FIG. **4**, but where two patch antenna elements **11** are connected to the central switching device **4** via connection lines **12**. The patch antenna elements **11** are placed closed to or in connection to the central switching device. What has been stated above in connection with FIG. **4** is also relevant for the embodiment of FIG. **5**.

FIG. **6** shows an example of an antenna device where a meander element **7** is connected to the central switching device **4** together with a whip antenna element **13**. The whip elements **13** and meander elements **7** can be connected directly to a RF feed device, shorted or coupled in parallel/series. Each element can act as an active radiating element, i.e., be connected directly to a RF feed device, or as a parasitic element, where there is no galvanic connection to a RF feed device. For example, the electrical length of the whip element **13** and/or the meander element **7** can be altered to tune the resonance frequency. There can be other parasitic elements, not shown, close to the whips and/or the meander for tuning and/or for changing the radiation pattern. In this way the radiation pattern can be mainly directed towards a desired direction. The whip element can be replaced by or combined with a helical antenna element.

Of course, the antenna device can include a switching device and any combination of the above described antenna elements forming a symmetrical or an unsymmetrical pattern of radiating elements. The antenna device can be adapted for operation in several frequency bands and for receiving and transmitting radiation of different polarization. In addition, the switching device **4** can be used to connect or disconnect discrete matching components. The invention is not limited to any specific shape of the individual antenna elements as the shapes can be chosen according to the desired function.

Close-by Operation Environments

Next, various physical operation environments that may affect the performance of the antenna device in accordance with the invention will be described. The antenna parameters, such as resonance frequency, input impedance, bandwidth, radiation pattern, gain, polarization, and near-field pattern, of a small-sized wireless communication device are affected by objects in the close-by environment of the device.

A small-sized wireless communication device, such as a mobile telephone, can be used in many different close-by environments. It can be held to the ear as a telephone, it can be put in a pocket (with the front toward the user or the back toward the user), it can be attached to a belt at the waist, or it can be held in the hand or placed on an electrically conductive surface. Many more operation environments may be enumerated. Common for all environments is that there may be objects in the close-by environment of the device, thereby affecting the antenna parameters of the device. Environments with different objects in the proximity of the device have different influence on the antenna parameters.

Two specific operation environments will in the following be specifically discussed.

The free space (FS) operation environment is obtained by locating the radio communication device in empty space, i.e. with no objects in the close-by environment of the device. Air surrounding the device is here considered to be free space. Many operation environments can be approximated by the free space environment. Generally, if the environment has little influence on the antenna parameters, it can be referred to as free space.

The talk position (TP) operation environment is defined as the position, in which the radio communication device is held to the ear by a user. The influence on the antenna parameters varies depending on the person holding the device and on exactly how the device is positioned. Here, the TP environment is considered as a general case, i.e. covering all individual variations mentioned above.

Radiation Related Parameters

Various radiation related parameters that may be affected by the physical operation environment and controlled by an antenna device in accordance with the invention will now be described in more detail.

Antennas for wireless communication devices experience detuning due to the presence of the user. For many antenna types, the resonance frequency drops considerably when the user is present, compared to when the device is positioned in free space. An adaptive tuning between free space and talk position can reduce this problem largely.

A straightforward manner to tune an antenna is to alter its electrical length, and thereby altering the resonance frequency. The longer the electrical length, the lower the resonance frequency. This is also the most straightforward way to create band switching, if the change in electrical length is large enough.

FIG. **7** shows a meander-like antenna structure **35** arranged together with a central switching device **36** including a plurality of switches **37**–**49**. The antenna structure **35** may be seen as a plurality of aligned and individually connectable antenna elements **50**–**54**, which are connectable to a feed point **55** through the switching device **36** and a feed line **56**. Feed point **55** is further connected to a low noise amplifier of a receiver circuitry (not shown) of a communication device, and hence, the antenna structure **35** operates as a receiving antenna. Alternatively, the feed point **55** is connected to a power amplifier of a communication transmitter for receiving an RF power signal, and hence the antenna structure **35** operates as a transmitting antenna. Optionally, the antenna structure **35** may be arranged for both transmission and reception.

A typical example of operation is as follows. Assume that switches **37** and **46**–**49** are closed and remaining switches are opened and that such an antenna configuration state is adapted for optimal performance when the antenna device is arranged in a hand-portable telephone located in free space. When the telephone is moved to talk position, the resonance frequency will be lowered due to the user and thus, in order to compensate for the presence of the user, switch **49** is opened, whereby the electrical length of the connected antenna structure is reduced and accordingly the resonance frequency is increased. This increase, with an appropriate design of antenna structure **35** and switching device **36**, will compensate for the reduction as introduced when the telephone is moved from free space to talk position.

According to the invention, all switching of the antenna elements **50**–**54** required for different purposes is centralized to the switching device **36** which is provided with a single feed line. Instead of tuning a detuned antenna, one can perform adaptive impedance matching, which involves letting the resonance frequency be slightly shifted and compensate this detuning by impedance matching.

An antenna structure can be fed at different locations. Each location has a different ratio between the E and H fields, resulting in different input impedances. This phenomenon can be exploited by switching the feed point, provided that the feed point switching has little influence on the resonance frequency of the antenna. When the antenna experiences detuning due to the presence of the user (or other object), the antenna can be matched to the feed line impedance by altering for example the feed point of the antenna structure. In a similar manner, RF ground points can be altered.

In FIG. **8** is schematically shown an example of such an implementation of an antenna structure **61** that can be selectively RF grounded at a number of different points spaced apart from each other. Antenna structure **61** is in the illustrated case a planar inverted F antenna (PIFA) mounted on a printed circuit board **62** of a radio communication device. Antenna **61** has a feed line **63** and N different spaced RF ground connections **64**. By switching from one RF ground connection to another, the impedance is slightly altered. As before all switching functions are centralized to a central switching device **60**.

Moreover, switching in/out parasitic antenna elements can produce an impedance matching, since the mutual coupling from the parasitic antenna element to the active antenna element produces a mutual impedance, which contributes to the input impedance of the active antenna element. If outer limits for the detuning of the antenna elements can be found, the range of adaptive tuning/matching that needs to be covered by the antenna device can be estimated.

The radiation pattern of a wireless terminal is affected by the presence of a user or other object in its near-field area. Loss-introducing material will not only alter the radiation pattern, but also introduce loss in radiated power due to absorption. This problem can be reduced if the radiation pattern of the terminal is adaptively controlled. The near-field radiation pattern can be directed mainly away from the loss-introducing object, which will reduce the overall losses.

A change in radiation pattern requires the currents producing the electromagnetic radiation to be altered. Generally, for a small device (e.g. a hand-portable telephone), there need to be quite large changes in the antenna structure to produce altered currents, especially for the lower frequency bands. However, this can be done by switching to another antenna type producing different radiation pattern, or to another antenna structure at another position/side of the PCB of the communication device.

Another way may be to switch from an antenna structure that interacts heavily with the PCB of the communication device (e.g., whip or patch antenna) to another antenna not doing so (e.g., loop antenna). This will change the radiating currents dramatically since interaction with the PCB introduces large currents on the PCB (the PCB is used as a main radiating structure).

Sensing of the Physical Operation Environment

According to the present invention, a sensor may be provided for detecting a physical property of a selected close-by environment and a control device may be provided for controlling the switching device, and thus the selective switching of the antenna structure between the various antenna configuration states, in dependence on the detected physical property. The sensor would in the general case not be part of the antenna device, but be located at the surface of the wireless terminal casing. In such an instance, the response of the sensor is received at the antenna module control device.

The sensing of the close-by environment can be performed in several manners. One manner can be to use sensors on different positions at the device. In this manner, objects on different sides of the device may be sensed. The sensors can be of different kinds, e.g., resistive, capacitive or inductive sensors.

Capacitive (negative reactance) or inductive (positive reactance) sensors change their reactance when objects with electrical properties differing from those of free space are close to them. Hence, these sensors may distinguish objects that do not have a large effect on the electric performance of the antenna, e.g. cloth. Capacitive sensors are in general more sensitive to dielectric materials. Capacitive sensors can be found in, e.g., elevator buttons. Inductive sensors, on the other hand, are in general more sensitive to conducting materials. Inductive sensors are often used in the automation industry, for sensing end points of metallic goods.

Another sensor type may be a heat detector for sensing body heat. Optical sensors, e.g., photo detectors, can also be used to detect objects in the close-by environment. Still other sensors that may be employed include pressure, inclination, orientation, or motion sensors, which may detect motion patterns and from them deduce different usage scenarios. Pressure sensors may detect whether the communication device is held by a person and the manner in which it is held.

Also, a measure of the reflection coefficient as measured after the power amplifier of the transmitter can be used to "sense" objects, which cause detuning of the antenna. This is possible since objects with electrical properties, which in the near-field area, i.e., close-by environment, of the antenna differ from those of free space, will influence the antenna-input impedance.

Yet another manner, in which the environment the device is in, may be determined, is the usage state itself, i.e., if the device is used for speech, and no hands-free unit is in use, the antenna is optimized for talk position.

Procedures for Controlling the Switching

The invention will be exemplified below by an algorithm, which uses any suitable sensed parameter such as the reflection coefficient as an optimization parameter. In the following example, the voltage standing wave VSWR is used.

A simple and easily implemented algorithm is a switch-and-stay algorithm, which is shown in the flow diagram of FIG. **9**. Here switching is performed between predefined states i=1, . . . , N (e.g. N=2, one state being optimized for FS and the other state being optimized for TP). A state i=1 is initially chosen, whereafter, in a step **65**, the VSWR is measured. The measured VSWR is then, in a step **66**, compared with a predefined limit (the threshold value). If this threshold is not exceeded the algorithm is returned to step **65**. If this threshold is exceeded, the algorithm proceeds to step **67**, whereby switching to a new state i=i+1 is performed. If i+1 exceeds N, switching is performed to state 1. After this step, the algorithm returns to step **65**.

Using such an algorithm, each state **1**, . . . , N is used until the detected VSWR exceeds the predefined limit. When this occurs, the algorithm steps through the predefined states until a state is reached which has a VSWR below threshold. Both transmitter and receiver antenna structures can be switched at the same time.

Next, the invention will be exemplified by a procedure using a look-up table for determining which antenna configuration state to switch to.

The sensor senses the close-by environment of the radio communication device. Different type of sensors will give different images of the close-by environment. For example, if capacitive or inductive sensors are used at various locations on the device, one may be able to tell towards which direction (as seen from the device) there is least influence from close-by objects. The antenna configuration state is then chosen so as to direct the main radiation towards this direction.

To each set of responses from the sensor(s), there is an associated antenna configuration state that preferably minimizes the influence of the objects, minimizing loss and maximizing radiated power. This can be implemented in the form of a look-up table.

A trial-and-error algorithm works only if an antenna related parameter is measured, for example the reflection coefficient. All sensors not sensing specific antenna parameters could use for example a look-up table type of procedure as described above. Of course, combinations can be used. One example of this is that non-antenna-related parameter sensors are used in order to find the antenna configuration state that works in the best manner possible. A trial-and-error algorithm may optionally fine-tune the antenna configuration state afterwards.

It will be obvious that the invention may be varied in a plurality of ways. Such variations are not to be regarded as a departure from the scope of the invention. All such modifications as would be obvious to one skilled in the art are intended to be included within the scope of the appended claims.

What is claimed is:

1. An antenna device provided for transmitting and/or receiving RF radiation, installable in and connectable to a portable radio communication terminal device, and comprising:

an antenna structure comprising a plurality of antenna elements capable of being connected to and disconnected from each other, said antenna structure being switchable between a plurality of predefined antenna configuration states, in each of which multiple ones of said plurality of antenna elements are connected to each other, and each of which being distinguished by a set of radiation parameters; and

a switching device provided for selectively switching said antenna structure between said plurality of predefined antenna configuration states,

wherein each of said plurality of predefined antenna configuration states is optimized for operation of the antenna device in said portable radio communication terminal device in a respective predefined physical operation environment external to said portable radio communication terminal device,

wherein said plurality of predefined antenna configuration states includes at least three antenna-configuration states, and said switching device is provided for receiving a measure indicating a change from a first one to a second one of said predefined physical operation environments and for switching said antenna structure from a first one to a second one of said plurality of predefined antenna configuration states, in dependence on said received measure, wherein said first predefined antenna configuration state is optimized for use of said antenna device in said portable radio communication terminal device in said first predefined physical operation environment, and said second predetermined antenna configuration state is optimized for use of said antenna device in said portable radio communication terminal device in said second predefined physical operation environment.

2. The antenna device of claim **1**, wherein said plurality of antenna elements includes at least three antenna elements.

3. The antenna device of claim **1**, wherein said plurality of antenna elements includes at least five antenna elements.

4. The antenna device of claim **1**, wherein said plurality of predefined antenna configuration states includes at least five antenna configuration states.

5. The antenna device of claim **1**, wherein at least some of said plurality of predefined antenna configuration states are optimized for operation of the antenna device in said portable radio communication terminal device in different frequency bands.

6. The antenna device of claim **1**, wherein said antenna structure in at least some of said plurality of predefined antenna configuration states have different electrical lengths.

7. The antenna device of claim **1**, wherein said switching device comprises a plurality of switches for connecting and disconnecting said plurality of antenna elements, and wherein said plurality of antenna elements are arranged one after another.

8. The antenna device of claim **1**, wherein said antenna structure in at least some of said plurality of predefined antenna configuration states have different feed positions and/or different ground positions.

9. The antenna device of claim **8**, wherein said at least some of said plurality of predefined antenna configuration states are identical except for the different feed positions and/or different ground positions.

10. The antenna device of claim **9**, wherein said antenna structure comprises a planar or patch antenna and a plurality of feed connectors and/or ground connectors.

11. The antenna device of claim **1**, wherein said antenna structure comprises two separate antennas of different type.

12. The antenna device of claim **11**, wherein said two separate antennas are a whip antenna or a patch antenna, and a loop antenna or a meander antenna.

13. The antenna device as claimed in claim **1**, wherein said switching device comprises a micro electromechanical system (MEMS) switch device.

14. The antenna device of claim **1**, wherein each of said respective predefined physical operation environments is defined by objects affecting RF radiation and located within a distance from said portable radio communication terminal device of less than ten wavelengths of said RF radiation.

15. The antenna device of claim **1**, wherein one of said plurality of predefined antenna configuration states is optimized for use of said antenna device in said portable radio communication terminal device in a position held to an ear of a user as a telephone, and one of said plurality of predefined antenna configuration states is optimized for use of said antenna device in said portable radio communication terminal device in a position held at a waist of the user.

16. The antenna device of claim **1**, wherein said switching device is connectable to a sensor device, which is capable of sensing and identifying each of said respective predefined physical operation environments external to said portable radio communication terminal device, and which is provided for sending said measure indicating a change from a first one to a second one of said predefined physical operation environments to said switching device.

17. The antenna device of claim **16**, wherein said antenna device comprises said sensor device.

18. The antenna device of claim **16**, wherein said sensor device is capable of sensing and identifying each of said respective predefined physical operation environments external to said portable radio communication terminal device by means of sensing resistance, capacitance, inductance, light, temperature, and/or pressure external to said portable radio communication terminal device, or inclination, orientation and/or motion of said portable radio communication terminal device.

19. The antenna device of claim **16**, wherein said sensor device is capable of sensing objects at two opposite sides of said portable radio communication terminal device simultaneously.

20. The antenna device of claim **1**, wherein said antenna device is further provided with an adaptive fine-tuning device capable of controlling switching by said switching device to find an optimum one of a plurality of fine-tuning antenna configuration states, where said plurality of fine-tuning antenna configuration states are variants of said second predefined antenna configuration state.

21. An antenna device provided for transmitting and/or receiving RF radiation, installable in and connectable to a portable radio communication terminal device, and comprising:

an antenna structure comprising a plurality of antenna elements capable of being connected to and disconnected from each other, said antenna structure being switchable between at least three predefined antenna configuration states, each of which being distinguished by a set of radiation parameters, and each of which being associated with a different operation environment external to said portable radio communication terminal device;

a switching device capable of selectively switching said antenna structure between said at least three predefined antenna configuration states; and

a control device provided for receiving a sensed resistance, capacitance, inductance, light, temperature, and/or pressure value external to said portable radio communication terminal device, for determining one of said different operation environments external to said portable radio communication terminal device depending on said sensed resistance, capacitance, inductance, light, temperature, and/or pressure value, and for controlling said switching device to switch said antenna structure to said one of said different operation environments determined depending on said sensed resistance, capacitance, inductance, light, temperature, and/or pressure value.

22. An antenna device provided for transmitting and/or receiving RF radiation, installable in and connectable to a portable radio communication terminal device, and comprising:

an antenna structure comprising a plurality of antenna elements capable of being connected to and disconnected from each other, said antenna structure being switchable between at least three predefined antenna configuration states, each of which being distinguished by a set of radiation parameters, and each of which being associated with a different operation environment external to said portable radio communication terminal device;

a switching device capable of selectively switching said antenna structure between said at least three predefined antenna configuration states; and

a control device provided for receiving a measure of inclination, orientation and/or motion of said portable radio communication terminal device, for determining one of said different operation environments external to said portable radio communication terminal device depending on said measure of inclination, orientation and/or motion of said portable radio communication terminal device, and for controlling said switching device to switch said antenna structure to said one of said different operation environments determined depending on said measure of inclination, orientation and/or motion of said portable radio communication terminal device.

23. In an antenna device installable in and connectable to a portable radio communication terminal device, and comprising an antenna structure comprising a plurality of antenna elements capable of being connected to and disconnected from each other, said antenna structure being switchable between at least three predefined antenna configuration states, each of which being distinguished by a set of radiation parameters, and each of which being associated with a different operation environment external to said portable radio communication terminal device, a method for transmitting and/or receiving RF radiation comprising:

receiving a detected physical property external of said portable radio communication terminal device;

determining one of said different operation environments external to said portable radio communication terminal device depending on said detected physical property;

controlling switching of said antenna structure to said one of said different operation environments determined depending on said detected physical property; and

transmitting and/or receiving RF radiation.

24. In an antenna device installable in and connectable to a portable radio communication terminal device, and comprising an antenna structure comprising a plurality of antenna elements capable of being connected to and disconnected from each other, said antenna structure being switchable between at least three predefined antenna configuration states, each of which being distinguished by a set of radiation parameters, and each of which being associated with a different operation environment external to said portable radio communication terminal device, a method for transmitting and/or receiving RF radiation comprising:

receiving a sensed resistance, capacitance, inductance, light, temperature, and/or pressure value external of said portable radio communication terminal device;

determining one of said different operation environments external to said portable radio communication terminal device depending on said sensed resistance, capacitance, inductance, light, temperature, and/or pressure value;

controlling switching of said antenna structure to said one of said different operation environments determined depending on said sensed resistance, capacitance, inductance, light, temperature, and/or pressure value; and

transmitting and/or receiving RF radiation.

25. In an antenna device installable in and connectable to a portable radio communication terminal device, and comprising an antenna structure comprising a plurality of antenna elements capable of being connected to and disconnected from each other, said antenna structure being switchable between at least three predefined antenna configuration states, each of which being distinguished by a set of radiation parameters, and each of which being associated with a different operation environment external to said portable radio communication terminal device, a method for transmitting and/or receiving RF radiation comprising:

receiving a measure of inclination, orientation and/or motion of said portable radio communication terminal device;

determining one of said different operation environments external of said portable radio communication terminal device depending on said measure of inclination, orientation and/or motion of said portable radio communication terminal device;

controlling switching of said antenna structure to said one of said different operation environments determined depending on said measure of inclination, orientation and/or motion of said portable radio communication terminal device; and

transmitting and/or receiving RF radiation.

(57) ABSTRACT

System and method for harvesting radio frequency power from a wireless transmitter includes; an antenna having an output voltage, a matching network coupled to the antenna, a booster circuit coupled to the matching network and having an output voltage, and adapted to amplify the output voltage of the antenna. Matching network is adapted to match a power transfer. A voltage stabilizer circuit is adapted to stabilize the booster circuit output voltage. Method includes, determining at least one operating mode and charging a slave device from a master wireless transmitter located within a predetermined distance from the system. A rechargeable battery in the system is charged from a wireless transmitter, and a slave device is connected to the system. The slave device is charged from the rechargeable battery in the system.

CROSS-REFERENCES TO RELATED APPLICATIONS

[0001] The present application claims benefit under 35 USC 119(e) of commonly assigned U.S. provisional application No. 61/364,731, filed Jul. 15, 2010, entitled "Method and System For Harvesting RF Signals and Wirelessly Charging A Device," and U.S. provisional application No. 61/364,739, filed Jul. 15, 2010, entitled "Wireless Battery Charger," the contents of all of which are incorporated herein by reference in their entirety.

BACKGROUND

[0002] The present invention relates generally to supplying power to portable devices. More specifically, some embodiments of the present invention relate to harvesting radio frequency (RF) signals to power portable devices.

[0003] In the world of nanotechnology and wireless communication and networking, power supply of electrical devices still is a matter of concern. Many scientists and researchers are working on various methods of production, transmission and storing energy. Portable devices powered by rechargeable batteries commonly need chargers or base stations that are connected by wire from a power grid. Such portable devices include cell-phones, personal digital assistants, smart-phones, tablets, and remote controls, among others. Some of these devices rely on radio frequency signals for communication purposes.

[0004] The existing wireless chargers have operation distance limitations which prevents them from being used in locations without access to the wired power grid. This means that the device to be charged has to be in locations where a power outlet exists so that the charger can be connected to a power outlet and then the device to be charged must be placed on it (or kept within a short distance from it).

[0005] RF signals in the air have very limited power. Thus, the output power of an RF signal harvester is in the range of micro and milli-watts. Yet, various low power electronic devices can be empowered with this power.

BRIEF SUMMARY

[0006] The present invention relates generally to supplying power to portable devices. More specifically, some embodiments of the present invention relate to harvesting radio frequency (RF) power to power portable devices.

[0007] According to one embodiment of the present invention, a system for harvesting radio frequency power from a wireless transmitter includes; (i) an antenna having an output voltage, (ii) a matching network coupled to the antenna, (iii) a booster circuit coupled to the matching network and having an output voltage, and adapted to amplify the output voltage of the antenna. The matching network is adapted to match a power transfer from the antenna to the booster circuit. The system for harvesting radio frequency power from the wireless transmitter further includes a voltage stabilizer circuit adapted to stabilize the output voltage of the booster circuit.

[0008] According to one specific embodiment, the system further includes a user selectable switch adapted to determine at least one operating mode, and a connector adapted to charge a slave device. At least one operating mode is adapted to charge the slave device from a master wireless transmitter located within a predetermined distance from the system.

[0009] According to another specific embodiment, the system further includes: (i) a user selectable switch adapted to determine at least one operating mode, (ii) a rechargeable battery adapted to be charged by the booster circuit, and (iii) a connector adapted to charge a slave device. The at least one operating mode is adapted to charge the rechargeable battery from a wireless transmitter located within a predetermined distance from the system and the rechargeable battery is adapted to charge the slave device.

[0010] According to another specific embodiment, the antenna is a wideband antenna. According to another specific embodiment, the antenna is a wideband circularly polarized micro-strip patch antenna.

[0011] According to another specific embodiment, the matching network is a resonant circuit tuned at a predetermined frequency. According to another specific embodiment, the booster circuit includes a multi-stage voltage multiplier circuit.

[0012] According to another specific embodiment, the system further includes a software executable on the master wireless transmitter and adapted to provide a user selectable amount of radio frequency power from the master wireless transmitter to the slave device.

[0013] According to another specific embodiment, the master wireless transmitter is adapted to transmit a user selectable file. The duration of the transmission corresponds to the amount of radio frequency power transmitted from the master wireless transmitter to the slave device.

[0014] According to another specific embodiment, the master wireless transmitter is chosen from one of the group of a cell-phone, a laptop, or a personal computer. According to another specific embodiment, the master wireless transmitter is adapted to transmit radio frequency power chosen from of one of the group of a Bluetooth signal, or a Wi-Fi signal.

[0015] According to another specific embodiment, the predetermined distance is about 1 meter. According to another specific embodiment, the predetermined distance is about 500 meters.

[0016] According to another specific embodiment, the wireless transmitter is adapted to transmit radio frequency power for the system. According to another specific embodiment, the wireless transmitter is adapted to transmit radio frequency power for the system in the form of one of the group of a GSM signal, or a Wi-Fi signal. According to another specific embodiment, the system is adapted to receive a signal having a power of at least −25 dBm.

[0017] According to one embodiment of the present invention, a method for harvesting radio frequency power from a wireless transmitter by a system including an antenna having an output voltage, a matching network coupled to the antenna, a booster circuit coupled to the matching network and having an output voltage, and a voltage stabilizer circuit, the method includes, matching a power transfer from the antenna to the booster circuit, amplifying the output voltage of the antenna, and stabilizing the output voltage of the booster circuit.

[0018] According to one specific embodiment, the method further includes determining at least one operating mode. According to another specific embodiment, the method further includes charging a slave device from a master wireless transmitter located within a predetermined distance from the system.

[0019] According to another specific embodiment, the method further includes charging a rechargeable battery in the system from a wireless transmitter located within a predetermined distance from the system, and connecting a slave device to the system. The slave device is charged from the rechargeable battery in the system.

[0020] A better understanding of the nature and advantages of the embodiments of the present invention may be gained with reference to the following detailed description and the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

[0021] FIG. **1** is a simplified block diagram showing a system for harvesting radio frequency power from a wireless transmitter in accordance with an embodiment of the present invention;

[0022] FIG. **2** is a simplified schematic diagram showing a matching circuit in accordance with an embodiment of the present invention;

DETAILED DESCRIPTION

[0027] According to the embodiments of the present invention, a system and method for harvesting radio frequency power from a wireless transmitter are described. The system may include a wireless charger that reuses the wasted power of RF signals in the environment. Although the output power of an RF signal harvester is in the range of micro and milliwatts, various low power electronic devices can be empowered with this low power. Some examples of such low power electronic devices may include: calculators, wireless chargers, low power electric devices (sensors, Remote Telemetry Units (RTUs) and the like), low power home appliances (remote controls, watches and the like), biomedical applications (empowering artificial organs such as implanted hearts), and robotics (robotic cells). In such applications, the RF signal harvester can replace batteries. In some applications, a high power transmitter may be placed in the field to provide the RF signals for the RF signal harvester. Using this system, one can charge up his/her portable device enough for a short operation time. For instance, if a cell-phone is to be charged, using the proposed method, the cell-phone will have enough battery power for a few calls.

[0028] Table 1 shows a comparison between an existing RF signal harvester and an RF signal harvester in accordance with embodiments of the present invention. Both of the harvesters were tested under the same conditions (i.e. normal movement, outdoor, and indoor environments). The approximated price of the prototype may be reduced by mass production.

TABLE 1

Harvester	Size (cm)	Output Voltage (mV)	Cost ($)	Special considerations
Commercialized Piezoelectric	4 × 7.5	0.25-0.4	100	Voltage is based on tested measurements
Proposed RF Signal Harvester (prototype)	2 × 3.5	0.15-0.5	11.90	Cost is approximated based on prototype assembly components

[0029] FIG. **1** is a simplified block diagram showing a system **100** for harvesting radio frequency power from a wireless transmitter in accordance with an embodiment of the present invention. System **100** may include an antenna **110**, a matching circuit **120**, a booster circuit **130** a charging unit **140**, a connector **150**, a switch **160**, and a housing **170**. Matching circuit **120** is coupled between antenna **110** and booster circuit **130**. Booster circuit **130** is coupled to charging unit **140**. The antenna **110**, matching circuit **120**, booster circuit **130**, and charging unit **140** may be contained in housing **170**, which may support connector **150** and switch **160**. Alternatively, antenna **110**, matching circuit **120**, booster circuit **130**, and charging unit **140** may be embedded in a low power wireless device. Connector **150** may include either a custom designed connector for each low power electronic device application or may include a general plug and a set of adaptor connectors to couple each low power electronic device application with the general plug. Switch may be user selectable and adapted to determine at least one operating mode to be described below. In one operating mode system **100** may further include an optional rechargeable battery **180**, which is coupled to charging unit **140** in housing **170**. In each operating mode, the switch either couples charging unit **140** to battery **180** and battery **180** to connector **150**, or couples charging unit **140** directly to connector **150**.

[0030] Antenna **110** may be a wideband circularly polarized micro-strip patch antenna. The polarization is selected to be circular so that the antenna can receive signals of all polarizations. Moreover, the antenna is wideband so that a wider range of signals can be harvested. Antenna **110** has an output voltage coupled to matching circuit **120**.

[0031] FIG. **2** is a simplified schematic diagram showing matching circuit **120** in accordance with an embodiment of the present invention. Matching circuit **120** may be tuned at a predetermined frequency, which, depending on the system of wireless communication, can be a Bluetooth frequency of 2.4 GHz or 5 GHz, or a GSM signal of frequencies from 900 MHz to 2 GHz) so that the mismatch losses are reduced and maximum power is delivered to booster circuit **130**. Matching circuit **120** may include a resonant circuit, which can help reduce noise and interference to other operating wireless systems. This noise and interference reduction is achieved by minimization of the reflected back signals due to mismatch. The matching circuit **120** may include a series RLC circuit **220**, **230**, **240** respectively. The design of matching circuit **120** is frequency dependent and may be designed in a way that power transfer losses are minimized.

[0032] Booster circuit **130** may either include diodes and capacitors or MOSFET transistors and capacitors to boost the output voltage of antenna **110** to voltage levels acceptable for charging a low power electronic device or battery **180**. FIG. **3** is a simplified schematic diagram showing a booster circuit **130***a* in accordance with a first embodiment of the present invention, which includes a multi-stage voltage multiplier circuit such as, for example, a six stage voltage multiplier circuit designed with capacitors **301**-**306** and schottky diodes **311**-**316**. Booster circuit **130***a* is designed in a way that changes in the value of capacitors does not affect the output of the booster significantly. In one example, capacitors **301**-**306** are each 1 pF.

[0033] In booster circuit **130***a*, the RF signal wave is rectified at its negative half of the cycle by C**301** and D**311**, and in its positive half by C**303** and D**312**. During the positive half-cycle, the voltage stored in C**301** from the negative half-cycle is transferred to C**303**, which causes the voltage of C**303** to be roughly two times the peak voltage of the RF source and is why this 2-stage portion of booster circuit **130***a* may be called a voltage doubler. The doubled voltage level is minus the turn-on voltage of the diode. Each stage of voltage multiplier contains one diode and one capacitor and operates in the manner described above. The number of stages determines the amount of multiplication (alternatively referred to herein as “amplification”).

[0034] FIG. **4** is an example of an output voltage response with respect to input RF power for the embodiment shown in FIG. **1**. The power of Bluetooth signals may not exceed 0 dBm so the higher powers are provided for lab measurement purposes. As can be observed from FIG. **4**, a voltage of 3 volts can be achieved using a Bluetooth signal to charge a battery or a low power device. As long as a potential deference across the battery is maintained, the current will flow through it, resulting in charging.

[0035] The booster circuit, which is a voltage multiplier, is used to amplify the output voltage of the antenna. Yet, the current gets reduced since the electric power follows the law of conservation of energy. Thus, the booster or the voltage amplifier may be designed in such a way that the power loss through the booster circuit is minimized. To achieve this goal, the booster circuit may include MOSFET transistors. FIG. **5** is a simplified schematic diagram showing a booster circuit **130***b*, in accordance with a second embodiment of the present invention, which includes a multi-stage voltage multiplier circuit such as, for example, a six stage voltage multiplier circuit designed with capacitors **501**-**506** and n-channel MOSFET transistors **511**-**516**. In this example, NMOS transistors are used, however, other types of transistors such as PMOS, and different combinations of PMOS and NMOS transistors may also be used.

[0036] Booster circuit **130***b* works on the same basic principles as booster circuit **130***a*. Booster circuit **130***b* is similar to, but not exactly the same as, booster circuit **130***a*. The difference with booster circuit **130***b* is that the output is more stabilized compared to booster circuit **130***b* since the turn-on voltage of the MOSFETs in booster circuit **130***b* is smaller than the turn-on voltage of the diodes included in booster circuit **130***a*. Thus, each multiplier stage in booster circuit **130***b* “pumps” current with less voltage loss resulting in better circuit power efficiency and the device technology may use standard CMOS technology, without requiring schottky diodes as in booster circuit **130***a*.

[0037] The output signal of booster circuit **130** is a DC signal, which can be used to charge a battery or empower a circuit. However, this DC signal should be stabilized. Thus, a charger unit may include a voltage stabilizer, usually a voltage regulator circuit, and an input-output port to interface between system **100** and the low power device to be charged. Currently, the size of the prototype is 5 cm by 0.4021 cm, which may be further reduced for production.

[0038] System **100** may include two different modes of operation in accordance with an embodiment of the present invention. FIG. **6** is a simplified block diagram showing a method **600** for harvesting a radio frequency power **620** from a master wireless transmitter **640** in accordance with an embodiment of the present invention, by using a first mode to charge a slave device **660** with system **100** coupled to slave device **660**. Master wireless transmitter **640** may include a device with wireless communication capabilities such as a cell-phone, laptop, PC, or any other device with wireless communication capability such as a base-station, router, and the like. The packet may be transmitted either via Wi-Fi or Bluetooth.

[0039] A packet is transmitted from master wireless transmitter **640** to system **100**. The packet may either be any file such as a photo, music, or the like type of file, from master wireless transmitter **640** or a specific file from a software designed for system **100**. The software provides a file for transmission at a predefined frequency of either 980 MHz or 2.4 GHz. The transmission duration of the file, which determines the amount of transferred power, can be selected by the user through the software interface. If an existing file is to be transmitted, its size determines the amount of the transmitted power. Slave device **660** may be a low power device with its own slave battery, such as a receiver phone, which charges by harvesting the energy of the transferred power packet received through system **100**. System **100** may or may not have embedded battery **180**. The longer the time of the connection, the higher the amount of the power that can be harvested by the slave device. The transmitting and receiving devices should be within a range of 1 meter from each other. After a certain time, the slave device charge reaches a point where it cannot be charged any further by system **100**.

[0040] In the second mode of operation, the system **100** gathers energy from the electromagnetic signals existing in its surroundings and charges a rechargeable battery **180** embedded in system **100**. After rechargeable battery **180** is charged, system **100**, including battery **180**, is coupled to the slave device, which then can be charged from rechargeable battery **180** in system **100**. By storing the energy obtained from these signals in a small rechargeable battery embedded in the system, enough power will always be available for emergency cases where no master device is readily available.

[0041] The RF signals existing in the environment can be either from a transmitter designed for system **100** or from the existing GSM, Wi-Fi, or the like signals in the air. As long as the existing signals have a minimum power of −35 dBm, they can be harvested by system **100**. This may sometimes give a user the freedom of being as far as 500 (or even more) meters from a GSM base station and still charge rechargeable battery **180** in system **100**. The limitation of this mode is that rechargeable battery **180** may not hold much power and may require frequent recharging, which may take extended time for recharging.

[0042] Embodiments of the present invention provides a system and method for harvesting radio frequency power from a wireless transmitter. The embodiments of the present invention are not limited by the type of transistor, PMOS, NMOS or otherwise, used to boost the radio frequency power. The embodiments of the present invention are not limited by the number of voltage multiplier stages used to boost the radio frequency power. It will be apparent to those with skill in the art that modifications to the above methods and apparatuses may occur without deviating from the scope of the present invention. Accordingly, the disclosures and descriptions herein are intended to be illustrative, but not limiting, of the scope of the invention, which is set forth in the following claims along with their full scope of equivalents.

What is claimed is:

1. A system for harvesting radio frequency power from a wireless transmitter comprising:

an antenna having an output voltage;

a matching network coupled to the antenna;

a booster circuit coupled to the matching network and having an output voltage, and adapted to amplify the output voltage of the antenna wherein the matching network is adapted to match a power transfer from the antenna to the booster circuit; and

a voltage stabilizer circuit adapted to stabilize the output voltage of the booster circuit.

2. The system of claim **1** further comprising:

a user selectable switch adapted to determine at least one operating mode; and

a connector adapted to charge a slave device wherein the at least one operating mode is adapted to charge the slave device from a master wireless transmitter located within a predetermined distance from the system.

3. The system of claim **1** further comprising:

a user selectable switch adapted to determine at least one operating mode;

a rechargeable battery adapted to be charged by the booster circuit; and

a connector adapted to charge a slave device wherein the at least one operating mode is adapted to charge the rechargeable battery from a wireless transmitter located within a predetermined distance from the system and the rechargeable battery is adapted to charge the slave device.

4. The system of claim **1** wherein the antenna is a wideband antenna.

5. The system of claim **1** wherein the antenna is a wideband circularly polarized micro-strip patch antenna.

6. The system of claim **1** wherein the matching network is a resonant circuit tuned at a predetermined frequency.

7. The system of claim **1** wherein the booster circuit includes a multi-stage voltage multiplier circuit.

8. The system of claim **2** further comprising a software executable on the master wireless transmitter and adapted to provide a user selectable amount of radio frequency power from the master wireless transmitter to the slave device.

9. The system of claim **2** wherein the master wireless transmitter is adapted to transmit a user selectable file wherein the duration of the transmission corresponds to the amount of radio frequency power transmitted from the master wireless transmitter to the slave device.

10. The system of claim **2** wherein the master wireless transmitter is chosen from one of the group of a cell-phone, a laptop, or a personal computer.

11. The system of claim **2** wherein the master wireless transmitter is adapted to transmit radio frequency power chosen from of one of the group of a Bluetooth signal, or a Wi-Fi signal.

12. The system of claim **2** wherein the predetermined distance is about 1 meter.

13. The system of claim **3** wherein the predetermined distance is about 500 meters.

14. The system of claim **3** wherein the wireless transmitter is adapted to transmit radio frequency power for the system.

15. The system of claim **3** wherein the wireless transmitter is adapted to transmit radio frequency power for the system in the form of one of the group of a GSM signal, or a Wi-Fi signal.

16. The system of claim **3** wherein the system is adapted to receive a signal having a power of at least −25 dBm.

17. A method for harvesting radio frequency power from a wireless transmitter by a system including an antenna having an output voltage, a matching network coupled to the antenna, a booster circuit coupled to the matching network and having an output voltage, and a voltage stabilizer circuit, the method comprising;

matching a power transfer from the antenna to the booster circuit;

amplifying the output voltage of the antenna; and

stabilizing the output voltage of the booster circuit.

18. The method of claim **17**, wherein the method further comprises determining at least one operating mode.

19. The method of claim **18**, wherein the method further comprises charging a slave device from a master wireless transmitter located within a predetermined distance from the system.

20. The method of claim **18**, wherein the method further comprises:

charging a rechargeable battery in the system from a wireless transmitter located within a predetermined distance from the system; and

connecting a slave device to the system wherein the slave device is charged from the rechargeable battery in the system.

(57) **ABSTRACT**

A system and device for harvesting various frequencies and polarizations of ambient radio frequency (RF) electromagnetic (EM) energy for making a passive sensor (tag) into an autonomous passive sensor (tag) adapted to collect and store data with time-stamping and some primitive computation when necessary even when an interrogating radio frequency identification (RFID) reader is not present (not transmitting). A specific source of ambient RF EM energy may include wireless fidelity (WiFi) and/or cellular telephone base stations. The system and device may also allow for the recharging of energy storage units in active and battery assisted passive (BAP) devices. The system could be a "smart building" that uses passive sensors with RF EM energy harvesting capability to sense environmental variables, security breaches, as well as information from "smart appliances" that can be used for a variety of controls and can be accessed locally or remotely over the Internet or cellular networks.

HARVESTING AMBIENT RADIO FREQUENCY ELECTROMAGNETIC ENERGY FOR POWERING WIRELESS ELECTRONIC DEVICES, SENSORS AND SENSOR NETWORKS AND APPLICATIONS THEREOF

CROSS REFERENCE TO RELATED APPLICATION

This application claims the benefit of U.S. Provisional Patent Application No. 60/705,636 filed on Aug. 4, 2005, the contents of which in its entirety is herein incorporated by reference.

BACKGROUND

1. Technical Field

The embodiments herein generally relate to wireless technology, and, more particularly, to harvesting ambient radio frequency (RF) electromagnetic (EM) energy for supplying, storing, recharging or supplementing the energy necessary to power active or passive wireless electronic devices, sensors and sensor networks.

2. Description of the Related Art

The ability of actively powered, battery assisted passive (BAP) and passive wireless sensors to remotely acquire, store and/or transmit data may open up a wide variety of medical, diagnostic, quality control, safety, supply chain, logistic and security applications. For an individual, the ability to determine, prior to consumption, whether a food item contains harmful bacteria or ingredients to which the individual is allergic is highly desirable. From a population's perspective, recent national and international events have increased the need for personal or distributed systems that can monitor and detect continuously in real-time or at periodic or irregular intervals in time, chemical agents, biological agents, radiological agents and other hazards locally or over wide geographical areas.

Examples of personal handheld wireless devices that can address these issues are cellular telephones (cell phones), personal data assistants (PDAs) and portable computers or notebooks (PCs). These are pervasive electronic devices that are networked via the Internet or cellular telephone networks. Generally, the abovementioned consumer electronic devices all require local energy storage (batteries) to provide mobility and portability, and do so until their local source of energy is depleted.

A new class of sensors such as Electronic Product Code (EPC) and Radio Frequency Identification (RFID) tags that include sensing capabilities are emerging as a generally inexpensive and effective means of addressing many wireless sensor applications such as, but not exclusively, cold-supply chain, food safety, quality control, environmental safety, medical, diagnostic, electro-immunoassays, consumer goods as well as homeland security, property and personal security applications.

Purely passive sensors, when actively interrogated by an RF transceiver (reader), use this received source of EM energy to power themselves up, to acquire readings from their sensors and then rebroadcast or reflect their specific identification code and sensor readings back to the interrogator. BAP tags use their batteries to acquire and store or log data from one or more sensors, but typically do not use their batteries to enhance their RF communication abilities. Active sensors have their own built in power source that can be used to acquire and store sensor readings at any time as well as

enhance the reception and transmission of RF communications. Generally, passive EPC and RFID tags equipped with one or more sensors will require a source of energy to measure and store their acquired information at times other than during active interrogation by a reader.

Because of the cost of the conventional sensors and sensor readers in particular, broad deployment of a sensor network over a large geographical area or widespread use by individuals is currently not particularly feasible. Generally, a considerable problem with large geographical deployment is that if the sensors are actively powered, their power sources need to be replaced when depleted, again adding to the cost. In addition, wear on sensors or sensor surfaces, generally requires sensors to be replaced on a regular basis further increasing the cost. In addition, imprecision in sensors generally requires cross validation to eliminate false positives, increasing the number of sensors that must be deployed for each application and thus also increasing the cost.

Accordingly, in view of the foregoing, there remains a need for low cost wireless sensors that can harvest ambient EM energy to power themselves up, acquire sensor data or recharge their power sources (batteries in the case of active sensors and batteries in BAP sensors).

SUMMARY

In view of the foregoing, the embodiments herein provide wireless RF addressable sensor network architectures for individuals, homes, industries, and homeland security where a wireless reader can supply RF power to and communicate with RF addressable tags that include sensors. Each active, BAP or passive tag can be equipped to harvest ambient EM energy from its environment allowing it to be autonomous: the tag can acquire and store data from its sensors independently of any particular reader event. The harvested ambient EM energy could, in addition, be used to transmit an alarm or "read me!" signal when a vital "sensor event" occurs, or to charge a battery on or near the tag. For example, the reader could be an RFID reader, a broadband wireless fidelity (WiFi) device, a cell phone, PDA, PC or a hybrid thereof comprising of a device adapted to read an RFID tag's unique identification and sensor information and bi-directionally communicate this information over the Internet or cellular telephone networks. The embodiments herein are also directed towards RF addressable tags with sensors that may be produced at costs lower than most types of active or passive tags conventionally available and furthers the state of the art by including ambient EM energy harvesting capabilities.

The RF addressable sensor tag combines RFID tag functionality with sensor functionality. The RF addressable sensor includes one or more antennas for communicating with the tag reader, one or more sensor elements, an RF power and communications interface, an RFID control module, and a sensor interface. The RFID control module includes logic to control RFID tag communications with an RFID tag reader. The RFID control module may also include logic and memory necessary to store and/or process the acquired sensor data.

The embodiments herein additionally furthers the current state of the art by adding an ambient EM energy harvesting sub-system to passive, BAP, or active wireless sensor tags. The harvested energy is used to provide power to the passive sensor or to provide power to the BAP or active sensor or for recharging an energy source on the active sensor tag or BAP sensor tag. This harvested energy is used by the sensor tag for: the facilitation of autonomous data collection and/or storage; the processing of acquired data; and the transmission of an alarm or "read-me!" signal when a vital sensor variable is above or below a critical threshold or vital sensor variables are above or below critical thresholds.

The embodiments herein are also adapted to identify WiFi and cellular base stations as sources of readily available, known frequency, ambient RF EM energy that can be harvested to provide energy to the sensor tag. The embodiments herein are also capable of identifying microwave band frequencies consistent with IEEE 521-1984 designations (Bands L, S, C, X, Ku, K, Ka, V, and W) as ambient RF EM energy that can be harvested to provide energy to the sensor tag.

In an instantiation of the embodiments herein, an RFID reader is used to communicate with nearby sensor tags that are being energized by harvested ambient RF EM energy supplied by a nearby WiFi router/transceiver or cellular base station. The WiFi router/transceiver or cellular base station not only supplies the ambient energy for the sensor tags, but also bi-directionally communicates and distributes the collected sensor tag data over the Internet or cellular telephone networks.

In an aspect of the embodiments herein, the RFID reader and WiFi router/transceiver are combined into a hybrid RFID-WiFi reader whereby the RFID reader sub-system communicates with nearby sensor tags that are being energized by harvested ambient RF EM energy supplied by the WiFi router/transceiver part of the hybrid RFID-WiFi reader. The WiFi router/transceiver part of the hybrid RFID-WiFi reader also facilitates the local and/or remote distribution of the collected sensor tag data over the Internet.

In another aspect of the embodiments herein, the RFID, WiFi router/transceiver, and cell phone technology are combined into a hybrid RFID-WiFi-cell phone reader whereby the RFID and/or WiFi reader sub-system communicates with nearby RFID sensor tags and the WiFi and cell phone subsystems facilitate local and remote access to the collected sensor tag data over the Internet or via the cellular telephone networks. The WiFi router/transceiver part of the hybrid RFID-WiFi-Cell phone reader is also the source of ambient energy available for harvesting by the sensor tags.

In another aspect of the embodiments herein, a source that radiates EM energy at a known frequency may be placed in the vicinity of the passive, BAP or active sensor tags for the sole purpose of supplying ambient RF EM energy at frequencies that these wireless sensors can harvest.

The energy harvesting system may include an antenna or an array of antennas to collect ambient EM energy having a single wavelength or a multitude of wavelengths of single polarization or arbitrary polarizations. In another aspect of the embodiments herein the energy harvesting antenna or antennas may be used to supplement the wireless tag's communication antenna or antennas. In another instantiation of the embodiments herein, the energy harvesting antenna or array of antennas connects to an impedance matching network and a rectifying and combining module before being fed to the power converting and/or conditioning module.

In yet another instantiation of the embodiments herein, the energy harvesting antenna or array of antennas may be designed to directly rectify the harvested energy (a rectenna or array of rectennas) and feed the rectified energy to an energy combining module that in turn feeds a power converting and/or conditioning module.

In another aspect of the embodiments herein, the energy harvesting power converting and/or conditioning module can supplement the wireless tag's RF transceiver power and thereby its communication capabilities. Furthermore, the embodiments herein preferably do not interfere with the communications between RFID readers and wireless RF addressable tags.

Generally, the embodiments provide a system comprising an ambient RF EM energy source; a sensor reader operatively connected to the ambient RF EM energy source; and a sensor in communication with the sensor reader, wherein the sensor comprises a control module comprising an energy harvesting controller; a tag module controlled by the control module; a sensor module controlled by the control module; an energy harvesting module controlled by the energy harvesting controller and adapted to wirelessly collect the ambient RF EM energy; and a power module adapted to provide a power supply for the control module, the power supply being generated by the collected ambient RF EM energy, wherein the energy harvesting controller is adapted to (i) assess power requirements of each of the tag and sensor modules, (ii) transfer power from the energy harvesting module to any of the tag and sensor modules, and (iii) charge a local energy storage device.

In one embodiment, the sensor further comprises an antenna module shared by the energy harvesting module and the tag module, wherein the antenna module comprises a rectification and impedance matching network; at least one RF pad operatively connected to the rectification and impedance matching network; and at least one antenna operatively connected to each of the at least one RF pad. In another embodiment, the tag module comprises a memory component; a RF communication interface operatively connected to the memory component; at least one RF pad operatively connected to the RF communication interface; and at least one antenna operatively connected to each of the at least one RF pad. The sensor module may comprise a memory component; a sensor interface and support sub-system operatively connected to the memory component; at least one sensor pad operatively connected to the sensor interface and support sub-system; and at least one antenna operatively connected to each of the at least one sensor pad. Alternatively, the sensor module comprises a memory component; a sensor interface and support sub-system operatively connected to the memory component; and at least one antenna operatively connected to sensor interface and support sub-system. Preferably, the control module further comprises a RFID tag controller; and a sensor processing controller operatively connected to the RFID tag controller.

In one embodiment, the energy harvesting module comprises an energy harvesting interface and support sub-system; at least one RF harvesting pad operatively connected to an energy harvesting interface and support sub-system; and at least one antenna operatively connected to each of the at least one RF harvesting pad. Alternatively, the energy harvesting module comprises an energy harvesting interface and support sub-system; at least one pair of RF harvesting pads operatively connected to the energy harvesting interface and support sub-system; and at least one rectenna operatively connected to each of the at least one pair RF harvesting pads. The energy harvesting interface and support sub-system may comprise a storage component; a power conditioner component operatively connected to the storage component; and a combiner operatively connected to the power conditioner, wherein the energy harvesting interface and support subsystem comprises a rectification and impedance matching network operatively connected to the combiner. Preferably, the power module comprises a power charger; a power source operatively connected to the power charger; and a voltage regulator operatively connected to the power source.

Additionally, the collected ambient RF EM energy enables the electronic device to be a fully autonomous data collector, alarm generator, event generator, data logger, and data processor independent of any other device. Moreover, the sensor reader may comprise any of a cell phone, a PDA, a PC reader, a RFID reader, a broadband WiFi device, and a combination thereof. Preferably, the power supply is generated only by the collected ambient RF EM energy. Furthermore, the sensor may be adapted to transmit a wireless signal to the sensor reader, and wherein the sensor reader is adapted to receive the transmitted wireless signal from the sensor. Also, the collected ambient RF EM energy facilitates transmission of the wireless signal when a selected sensor variable meets a predetermined threshold. In one embodiment, the ambient RF EM energy source comprises a WiFi router adapted to allow the sensor reader to communicate over the Internet.

Alternatively, the ambient RF EM energy source comprises a hybrid WiFi router transceiver adapted to allow the sensor reader to communicate over the Internet. In another embodiment, the sensor is a RF ambient EM energy harvesting sensor and is arranged with a plurality of other the sensors each adapted to collect data for climate control, security alarms, environmental alarms, and information gathering from other devices located within a communicable distance from the sensor, wherein all of the sensors are adapted to be any of locally and remotely monitored via any of the Internet and a cell phone network.

These and other aspects of the embodiments herein will be better appreciated and understood when considered in conjunction with the following description and the accompanying drawings. It should be understood, however, that the following descriptions, while indicating preferred embodiments and numerous specific details thereof, are given by way of illustration and not of limitation. Many changes and modifications may be made within the scope of the embodiments herein without departing from the spirit thereof, and the embodiments herein include all such modifications.

BRIEF DESCRIPTION OF THE DRAWINGS

The embodiments herein will be better understood from the following detailed description with reference to the drawings, in which:

FIG. **1** is a schematic diagram illustrating an example of ambient RF EM energy harvesting for gathering, accumulating, and storing energy and powering passive wireless sensors or sensor tags and/or recharging BAP and/or active wireless sensors or sensor tags all of which are equipped with ambient EM energy harvesting technology according to an embodiment herein;.

FIG. **2** is a schematic diagram illustrating the deployment of wireless addressable sensor tags with on-board EM energy harvesting technology in a home, business, office, warehouse, or building according to an embodiment herein;

FIG. **3**A is a schematic diagram illustrating an example of a WiFi wireless router/transceiver, connected to the Internet, bathing passive and/or BAP and/or active wireless sensor tags with energy at a known frequency or known frequencies according to an embodiment herein;

FIG. **3**B is a schematic diagram illustrating an example of a hybrid RFID-WiFi wireless router comprising an RFID tag reader module combined with a WiFi router/transceiver connected to the Internet according to an embodiment herein;

FIG. **3**C is a schematic diagram illustrating an example of a hybrid RFID-WiFi-cell phone wireless router comprising an RFID tag reader module, a WiFi router/transceiver module that facilitates connection to the Internet, and a cell phone module that facilitates connection to cellular telephone networks according to an embodiment herein;

FIG. **4**A is a schematic diagram illustrating an example of an RFID sensor tag equipped with an energy harvesting subsystem that initiates an alarm or "read me!" signal when a measured variable or combination of measured variables exceeds a predefined critical threshold according to an embodiment herein;

FIG. **4**B is a schematic diagram illustrating an example of an RFID sensor tag equipped with the energy harvesting sub-system logging (writing to memory) the sensed data according to an embodiment herein;

FIG. **5**A is a block diagram illustrating a passive wireless RF addressable tag module with a sensor module;

FIG. **5**B is a block diagram illustrating an active wireless RF addressable tag module with a sensor module;

FIG. **6** is a block diagram illustrating an EM energy harvesting sub-system architecture according to an embodiment herein;

FIG. **7**A is a block diagram illustrating a passive wireless RF addressable tag with a sensor module combined with an EM energy harvesting sub-system architecture according to an embodiment herein;

FIG. **7**B is a block diagram illustrating an active wireless RF addressable tag architecture with a sensor module combined with an illustrative EM energy harvesting sub-system architecture according to an embodiment herein;

FIG. **8** is a block diagram illustrating a passive wireless RF addressable tag architecture with a sensor module, an EM energy harvesting sub-system, and an antenna module that could be used for RF communication with a reader as well as to harvest ambient EM energy according to an embodiment herein;

FIG. **9**A is a block diagram illustrating an example of an EM energy harvesting architecture comprising an antenna or an array of antennas with associated rectification and matching networks according to an embodiment herein; and

FIG. **9**B is a block diagram illustrating an example of an EM energy harvesting architecture comprising a rectenna (rectifying antenna) or an array of rectennas with rectification and matching built into each rectenna according to an embodiment herein.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

The embodiments herein and the various features and advantageous details thereof are explained more fully with reference to the non-limiting embodiments that are illustrated in the accompanying drawings and detailed in the following description. Descriptions of well-known components and processing techniques are omitted so as to not unnecessarily obscure the embodiments herein. The examples used herein are intended merely to facilitate an understanding of ways in which the embodiments herein may be practiced and to further enable those of skill in the art to practice the embodiments herein. Accordingly, the examples should not be construed as limiting the scope of the embodiments herein.

As mentioned, there remains a need for low cost wireless sensors that can harvest ambient EM energy to power themselves up, acquire sensor data or recharge their power sources (batteries in the case of active sensors and batteries in BAP sensors). The embodiments herein achieve this by providing a technique for harvesting ambient RF EM energy for supplying, storing, recharging or supplementing the energy necessary to power active, BAP or passive wireless electronic devices, sensors and sensor networks, allowing them to become autonomous "data loggers" and/or empowering them to transmit their unique identification and sensor information when a sensed variable or a combination of sensed variables exceeds a threshold and triggers a vital "sensor event".

More specifically, the embodiments provide a system and device for harvesting various frequencies and polarizations of ambient RF EM energy for making a passive sensor (tag) into an autonomous passive sensor (tag) adapted to collect and store data with time-stamping and some primitive computation when necessary even when an interrogating RFID reader is not present (not transmitting). A specific source of ambient RF EM energy may include WiFi. The system and device may also allow for the recharging of energy storage units in active and BAP devices. The system could be a "smart building" that uses passive sensors with RF EM energy harvesting capability to sense environmental variables, security breaches, as well as information from "smart appliances" that can be used for a variety of controls and can be accessed locally or remotely over the Internet or cellular telephone networks. Referring now to the drawings, and more particularly to FIGS. **1** through **9**B, where similar reference characters denote corresponding features consistently throughout the figures, there are shown preferred embodiments.

The embodiments herein relate to ambient EM energy harvesting for powering passive wireless sensors and for recharging energy storage devices on active or BAP wireless sensors. The RF frequency band from 3 KHz to 300 GHz, and a subset of this band, the Microwave Frequency Band from 1 GHz to 110 GHz (as designated in IEEE 521-1984) are identified as the most ubiquitous sources of ambient energy available for energy harvesting.

The embodiments herein furthers the current state of the art by focusing on RFID sensor tag technologies that may be purely passive (i.e., no on-board power supply but may have on-board energy storage devices) and/or active (i.e., having on-board energy storage as the power supply) and/or BAP (i.e., also having on-board energy storage as the power supply). The distinction between active and BAP wireless sensors is made here: an active tag uses its local power source to power up its sensors and boost its RF receive and transmit communications power while a BAP tag uses its local power source to power up and collect data from its sensors alone.

In particular IEEE standards 802.11a, 802.11b, and 802.11g and WiFi routers/transceivers used in homes, businesses, warehouses, stores and in towns or cities transmit a known wavelength (or frequency) in the S-band (2 GHz to 4 GHz) and the C-band (4 GHz to 8 GHz). This source of energy can be optimally harvested with a combination of appropriately designed antenna or antennas and rectenna or rectennas, impedance matching circuits, voltage regulation circuits and energy storage devices and can be used for supplying energy to wireless sensors, be they passive, BAP or active.

EM energy transmitted by cell phone towers (cellular base stations) is also designated as a ubiquitous source of energy of known wavelength (or frequencies in the 800 MHz to 1.9 GHz), and may likewise be optimally harvested and processed for supplying energy to wireless sensors, be they passive, BAP or active.

In addition a further improvement to the state of the art and provided by the embodiments herein is a hybrid RFID-WiFi transceiver that combines an RFID sensor tag reader and a WiFi router/transceiver into a device that can provide ambient EM energy to RFID sensor tags, read their unique identity and data from the tag and transmit this data over the Internet. The hybrid RFID-WiFi transceiver enables remote query of RFID sensor tags' identity and data via the Internet.

An additional improvement to the state of the art provided by the embodiments herein is a hybrid RFID-WiFi-cell phone transceiver that combines an RFID sensor tag reader, a WiFi router/transceiver, and a cell phone into a device that can provide ambient EM energy to RFID sensor tags, read their unique identity and data from the tag and transmit this data over the Internet and/or cellular telephone networks. The hybrid RFID-WiFi-cell phone transceiver enables remote query of RFID sensor tags' identity and data over the Internet as well as via cellular telephone networks.

The embodiments herein further improves upon the state of the art by making it possible for purely passive sensors to harvest available EM energy from their environment, and locally accumulate and store this energy so that passive tags become autonomous; i.e., they can log data and they can transmit an alarm or "read me!" signal to a nearby reader when a critical sensor event occurs or when a critical combination of sensor events occur or when a sensor level or combination of sensor levels has crossed a threshold.

FIG. **1** is an illustrative scenario of some of the forms of ambient EM energy that may be available for harvesting by passive RF addressable sensor tags **110** with energy harvesting capability. The ambient EM energy bathing the environment **115** in which the tags **110** are placed can come from a number of different sources including broadband WiFi routers/transceivers 120 (including but not limited to IEEE 802.1x, IEEE 802.15.4 "Zigbee®" electronic devices, Bluetooth® telecommunication equipment, HomeRF® computer hardware/software, HiperLAN/1 and HiperLAN/2), an EM transmitter **130** continuously or periodically radiating a known frequency (or frequencies), Microwave IEEE 521-1984 or cell phone base stations **140**, satellite transceivers **150**, wireless tag sensor readers **160**, and cell phones, PDAs or PCs **170**.

The energy that each of these sources contribute to the total amount of ambient EM energy available for harvesting by the antenna (not shown) of the tag **110**, $P_{RF}(t)$ **125**, **135**, **145**, **155**, **165**, **175** respectively, is a function of time, position/distance, frequency, solid angle and polarization state:

$$P_{RF} = \frac{1}{f_2 - f_1} \int_{f_1}^{f_2} \int_0^{4\pi} \Phi(\Omega, f, t) A_{eff}(\Omega, f) d\Omega df$$

where $\Omega$is the solid angle in steradians, $\Phi(\Omega f,t)$ is the time-varying frequency and angle-dependent incident power density and $A_{eff}$is the angle-, frequency-, and polarization-dependent effective area of the antenna.

The available power $P_{RF}(f_i)$ at any frequency f_i is an alternating current (ac) signal that must be converted to a direct current (dc) signal by a nonlinear device or rectifier (not shown) before being summed together with all other energy sources of different frequencies, $f_{1 \ldots n}$, which have been similarly rectified. The dc power, P_{dc} at a single frequency, f_i is given by:

$$P_{dc}(f_i) = P_{RF}(t, f_i) n[P_{RF}(t, f_i), \beta]$$

where $\eta = P_{dc}/P_{RF}$ is the total received rectified and summed power conversion efficiency (including the loss due to reflected power), and $\beta(P_{dc}, f_i,)$ represents the extent to which the rectifying device (not shown) and the antenna are impedance matched at the received dc power level, P_{dc} and frequency f_i.

The anticipated ambient power densities that can be harvested and converted to dc power at useful voltage levels is approximately in the range 10^{-1} mW/cm^2 (the FCC exposure limit for 880 MHz and 1990 MHz) to 10^{-6} mW/cm^2. One skilled in the art can optimize the harvested dc power, P_{dc} by appropriately adjusting the parameters A_{eff} and/or the parameters η and, β.

FIG. **2** is an illustrative example of a "smart home" 200 where RF addressable sensor tags **110** with energy harvesting capability are mounted on windows **210**, a door **220**, and in the attic **230**. Wired **270** or satellite transceiver **150** broadband Internet access is connected to a WiFi router **120** which bathes the smart house **200** in RF energy. Alternatively, an RF EM source **130** of known frequency continuously or periodically radiates energy specifically for the purpose of providing energy for the RF addressable sensor tags **110** with energy harvesting capability. An RFID tag reader **160** or a cell phone, PDA or PC **170** can read the unique identity and sensor data from each passive sensor tag **110**. The sensor tags **110** can be used to monitor environmental conditions such as temperature, humidity, carbon monoxide levels, radiation levels or smoke inside the house and the data read from the sensor tags **110** may be used to control HVAC systems or sound alarms when sensor thresholds are exceeded. The same sensor tags **110** can be used to detect unwanted intruders via vibration detectors, breakage detectors and open door detectors. Accordingly, the data from such sensors **110** can be used in a home security monitoring device. Similarly, addressable sensor tags **110** with energy harvesting capability can be placed on home appliances such as refrigerators, stoves, hot water heaters and gas/oil furnaces to monitor their operating state. Since the smart house **200** is connected to the Internet **270**, **150**, and/or via a cell phone **170**, all sensor data can be accessed locally and/or remotely over existing Internet and/or cellular telephone networks. Again, these sensors **110** harvest ambient energy from any or all of the available modes of RF EM energy bathing the house **200**. This energy could be used to power the passive sensor tags **110** or recharge batteries or other power sources associated with active or BAP tags **110**.

FIG. **3**A illustrates an example of a WiFi router/transceiver **120** connected to the Internet **270**, bathing passive, BAP or active wireless sensor tags **110** with energy at a known frequency **125**. This particular source of ambient energy supplies the passive sensor tag **110** with power or facilitates recharging batteries or other on-board or nearby energy storage devices. A single tag reader **160** (or a plurality of tag readers) is adapted to interrogate **330** each uniquely identifiable sensor tag **110** for information about its particular sensor tag reading(s) **320** and pass this information to the WiFi router/transceiver **120** via a direct connection **310** to make it locally or remotely accessible via the Internet and/or cell phone networks. This particular source of ambient energy can supply the passive sensor tag **110** equipped with energy harvesting capability with power for autonomous data collection and storage, or facilitate recharging batteries or other energy storage devices.

FIG. **3**B illustrates a hybrid RFID-WiFi wireless router **340** comprising an RFID tag reader module combined with a WiFi router/transceiver connected to the Internet **270**. This hybrid RFID-WiFi reader/module **340** provides a source of ambient energy **125** which the sensor tag **110** can harvest to supply itself with power to become an autonomous sensor **110** able to collect and save data as well as send out an alarm if its reading(s) has/have crossed a predefined threshold or a combination of predefined thresholds. The harvested energy can also facilitate recharging batteries or other energy storage devices associated with each tag **110**. The hybrid RFID-WiFi router/transceiver **340** periodically or sporadically interrogates **330** each uniquely identifiable sensor tag **110** for its data, and each uniquely identifiable sensor tag **110** rebroadcasts **320** its particular sensor(s) reading(s) back to the RFID-WiFi router/transceiver **340** which makes that data accessible over the Internet.

FIG. **3**C illustrates a hybrid RFID-WiFi-Cell phone router/transceiver **350** comprising an RFID tag reader module, a WiFi router/transceiver module and a cell phone module. This hybrid RFID-WiFi-Cell phone reader module **350** provides a source of ambient energy **125** which the sensor tag **110** can harvest to supply itself with power to become an autonomous sensor **110** able to collect and store data as well as send out an alarm if its reading(s) has/have crossed a predefined threshold or a combination of predefined thresholds. The harvested energy can also facilitate recharging batteries or other energy storage devices associated with each tag **110**. The hybrid RFID-WiFi-Cell phone router/transceiver **350** periodically or sporadically interrogates **330** each uniquely identifiable sensor tag **110** for its data, and each uniquely identifiable sensor tag **110** rebroadcasts **320** its particular sensor(s) reading(s) back to the hybrid RFID-WiFi-Cell phone router/transceiver **350** which is connected to the Internet **270** and makes that data accessible over the Internet as well as over cellular telephone networks.

FIG. **4**A illustrates an RFID temperature sensor tag **410** equipped with energy harvesting capability. Ambient EM energy **430** is harvested by the sensor tag **410**. This harvested energy is used by the tag **410** to continuously, periodically, or sporadically measure its sensor's value and compare that value with a pre-programmed threshold **470**. If this threshold is crossed, the tag **410** initiates and broadcasts an alarm or "read me!" signal **460** which is read by an RFID reader **160** or cell phone, PDA, or PC reader **170** along with its unique identification number. In this particular illustrative example the tag **410** senses temperature, but in general, the sensor or sensors of the tag **410** could measure a variety of environmental or physical variables. The unique identification and sensor data of the tag **410** can then be read by a standalone RFID reader **160** or by a cell phone, PDA, or PC reader **170**.

FIG. **4**B illustrates an RFID temperature sensor tag **410** equipped with energy harvesting capability that uses ambient EM energy **430** to provide a continuous, periodic, or sporadic source of power to the RFID temperature sensor tag **410**. The sensor tag **410** logs data to local memory **480** and can periodically or sporadically initiate and broadcast a signal **485**, which can be read by the RFID reader **160**. The RFID reader **160** can also periodically or sporadically initiate a read **490** of the unique identification and data of the tag **410**. In this particular illustrative example the tag **410** senses temperature, but in general, the sensor or sensors of the tag **410** could measure a variety of environmental or physical variables. The unique identification and sensor data of the tag **410** can then be read periodically or sporadically either when a sensor event initiates a "read me!" signal **485**, or when a standalone RFID reader **160** or a cell phone, PDA, or PC reader **170** initiates a read cycle **490**.

FIG. **5**A illustrates a passive wireless RF addressable sensor tag **500***a*, which may be used as a basis for designing the embodiments herein. The passive RFID tag **500***a* includes three main modules: the control module **510**, the tag module **540**, and the sensor module **520**. The control module **510** has an RFID tag controller **514** and a sensor processing controller **512** that can communicate with each other. The RFID tag controller **514** communicates with and controls the tag module **540**. The tag module **540** has on-board memory **542** and an RF communication interface **546**. The memory **542** holds the unique identification number and additional information **544** associated with that particular sensor tag **500***a*. The RF communication interface **546** has a voltage regulator **548** and a communication interface **550**. The RF communication interface **546** connects to a single antenna or a multitude of antennas **556** through an RF pad or a multitude of RF pads **554**. The sensor module **520** has its own memory **522** and a sensor interface and support sub-system **526**. The memory **522** stores the sensor data table **524** that include sensor calibration parameters, lookup tables as well as data collected from the sensor or sensors of the sensor tag **500***a*. The sensor interface and support sub-system **526** has a voltage and/or current reference generator **528**, an integrated temperature sensor **530** and an analog to digital converter **532**. An external sensor or a multitude of external sensors **536** are connected to the sensor interface and support sub-system **526** via a sensor pad or a multitude of sensor pads **534**.

FIG. **5**B illustrates an active or BAP wireless RF addressable sensor tag **500***b*, which may be used as a basis for designing the embodiments herein. In addition to all of the components described with FIG. **5**A above, there is also an active source module **560** which communicates with the control module **510**. The active source module **560** includes a power source **564** which could be replaceable and/or rechargeable, and voltage regulation circuitry **562** which regulates the voltage and/or current necessary to recharge the power source **564** and supply power to the remainder of the sensor tag **500***b*.

FIG. **6** is an illustrative example of a block diagram of the embodiments herein as it relates to the harvesting of ambient EM energy for supplying, storing, recharging, or supplementing the energy necessary to power active, BAP or passive wireless electronic devices, sensors and sensor networks. The EM energy harvesting sub-system architecture **600** comprises a single antenna **650**, rectifier and matching network **638** or an array of antennas **650**, rectifiers and matching networks **638**, a combiner **636**, a power conditioner **634**, and an energy storage device **632**. The energy harvesting controller **610** communicates bi-directionally with the energy harvesting module **620** and RFID tag controller **514**, wherein both the energy harvesting controller **610** and energy harvesting module **620** may or may not be integrated into an RFID sensor chip (not shown), depending on the particular application. The energy harvesting controller **610** sporadically, periodically or continuously controls and monitors the state of the energy harvesting module **620**. The energy harvesting module **620** includes an energy harvesting interface and support sub-system **630** that connects to an external energy harvesting antenna or multitude of external energy harvesting antennas **650** through an RFh (RF harvesting) pad or a multitude of RFh pads **640**.

The antenna or multitude of antennas **650** may be designed to collect ambient EM energy at either a single frequency f_1, a range of frequencies f_i, i=1, 2, 3 . . . N, or a specific set of frequencies, for example $f_{\{i,j,k\}l}=\{13.56$ MHz, 438 MHz, 928 MHz, 2.54 GHz$\}$. Moreover, the polarization state of the energy within the aperture of a single energy harvesting antenna or a multitude of energy harvesting antennas **650** can be arbitrary. Furthermore, the aperture or effective area A_{eff} of an energy harvesting antenna or multitude of energy harvesting antennas **650** can be optimized for a wavelength, and/or a range or set of wavelengths of the received EM energy, and can be readily accomplished by those skilled in the art.

The EM energy harvested by an energy harvesting antenna or a multitude of energy harvesting antennas **650** presents an ac signal or a multitude of ac signals to the rectification and matching network **638**. The matching network **638** is preferably designed to optimally match the frequency, polarization state and signal strength (power) dependence $\beta(P_{dc},f_i)$ of the output impedance of the harvesting antenna(s) **650** and the input impedance of the rectification element or elements **638** to ensure maximum power transfer or harvesting efficiency. The rectifier or rectifiers **638** convert the ac signal(s) into a dc or voltage signal(s).

The combiner **636** takes its input from the output of the rectification and matching network **638** and combines the currents or voltages in any combination of series or parallel connections in order to provide the necessary quantity of dc power for passive, BAP, or active sensor tag operation. The conditioner **634** takes the dc power from the combiner **636** and converts this dc power into a specified voltage level and/or current level with efficiency η by using circuit techniques known by those skilled in the art. The voltage and/or current level may be determined by the requirements of the local energy storage device **632** and/or the active source module **560**. The storage device **632** acts as local storage and may be implemented using any or a combination of capacitors, supercapacitors, plastic batteries, polymer batteries, Li-Ion batteries, or any rechargeable energy storing technology that can be integrated within the energy harvesting module **620**.

FIG. **7**A is an illustrative block diagram of an instantiation of a passive sensor tag **110***a* that includes a control module **710**, a tag module **540**, a sensor module **520**, and an energy harvesting module **620**. The energy harvesting controller **610** is shown here as being part of the control module **710** and communicates with the RFID tag controller **514** and the sensor processing controller **512**. The energy harvesting controller **610** is responsible for assessing the power needs of the tag module **540** and the sensor module **520** and can divert power from its storage element **632** to the tag module **540** and the sensor module **520** as necessary.

FIG. **7**B is an illustrative block diagram of an instantiation of a BAP or active sensor tag **110***b* that includes the energy harvesting module **620**. The difference between this sensor tag **110***b* of FIG. **7**B and sensor tag **110***a* of FIG. **7**A is the addition of the power module **720** whose purpose is to control and distribute power to the control module **730**, the tag module **540**, and the sensor module **520** in a BAP or active sensor tag **110***b*. The power module **720** includes, but is not limited to, a charger **725**, a power source **564**, and voltage regulation **562**.

The charger **725** controls the continuous, periodic, or sporadic charging of energy storage devices, in particular the power source **564** which may be a capacitor, supercapacitor, plastic battery, polymer battery, Li-Ion batteries, or any rechargeable energy storage technology. The voltage regulation sub-system **562** regulates the voltage and/or current that is needed to charge/recharge the power source **564** or divert power to the tag module **540** and/or the sensor module **520** as determined by the control module **730**.

FIG. **8** is a block diagram of another illustrative example of a sensor tag **110***c*with EM energy harvesting capability. As with the sensor tag **110***a* of FIG. **7**A and sensor tag **110***b* of FIG. **7**B, the sensor tag **110***c* of FIG. **8** comprises a control module **730**, a sensor module **520**, a tag module **830**, an energy harvesting module **810**, and an antenna module **840**. The tag module **830** differs from the tag module **540** of FIGS. **5**A, **5**B, **7**A, and **7**B in that there are no RF pads **554** and no antennas **556**. The remaining functionality of the tag module **830** is the same as described above.

Likewise, the energy harvesting module **810** differs from the energy harvesting module **620** of FIGS. **6**, **7**A, and **7**B in that there are no RF pads **554** and no RF antenna **556**, nor are there RFh pads **640** or energy harvesting antennas **650** associated with this module **810**. The remaining components, storage **632**, conditioner **634**, and combiner **636** have the same functionality as described above.

The antenna module **840** serves both the tag module **830** and the energy harvesting module **810**. An antenna or a multitude of antennas **846** are used for both RF EM energy harvesting and for bidirectional RF communications with an RFID, hybrid RFID-WiFi or hybrid RFID-WiFi-Cell phone reader. The antenna or antennas are designed to optimize RFID read range as well as to optimize A_{eff}. Each antenna **846** is connected via an RF pad **844** to the rectification and matching network **842**.

The rectification and matching network **842** is used to match the impedance of the antenna(s) **846** to that of the rectifier(s) as described above. In the context of FIG. **8**, the rectification and matching network **842** includes the rectifier(s). Moreover, those skilled in the art would readily understand that diodes, transmission lines, microstrip elements, and surface mount components could be further included in the rectification and matching network **842** in order to provide the rectifier(s). Since this network **842** also allows RF communications to occur, frequencies corresponding to those used by the RFID, RFID-WiFi, or RFID-WiFi-Cell phone reader (not shown in FIG. **8**) are preferably isolated and directed to the communication interface **550** on the tag module **830**. The harvested EM energy, once rectified, is sent first to the combiner **636**, then to the conditioner **634**, and finally to storage **632** as described above.

FIG. **9**A is an illustrative example of a block diagram of one of many possible designs for an EM RF energy harvesting antenna array module **910** in accordance with the embodiments herein, with the functionality of the various components included therein as previously described above. FIG. **9**B is an illustrative example of a block diagram of an alternate method for harvesting EM RF energy. In this aspect of the embodiments herein, an EM RF energy harvesting rectenna array module **950** is provided as a possibly more efficient way to harvest ambient EM RF energy.

In FIG. **9**B, an array of rectennas **970**, $\text{Rectenna}_1, \ldots, \text{Rectenna}_n$, each comprise a pair of antennas **982**, **984**, optimized to collect a broad range of RF frequencies having time-varying polarization states, directly integrated with an impedance matched rectifier **980**. Each rectenna **970** could be made up of two interdigitated antennas, one with a clockwise winding **982**, the other with a counterclockwise winding **984**, with the rectifier **980** connected between the two inner ports of the antennas. The rectified signals are collected from the two outermost ports of the rectenna **970** and connected to pads $\text{RHh}_1, \ldots, \text{RFh}_n$, **960**.

The techniques provided by the embodiments herein may be implemented on an integrated circuit (IC) chip or using printable electronic technologies (not shown). The chip or printable electronic circuit design is created in a graphical computer programming language, and stored in a computer storage medium (such as a disk, tape, physical hard drive, or virtual hard drive such as in a storage access network). If the designer does not fabricate chips or printable electronic circuits or the photolithographic masks used to fabricate chips or printable electronic circuits, the designer transmits the resulting design by physical means (e.g., by providing a copy of the storage medium storing the design) or electronically (e.g., through the Internet) to such entities, directly or indirectly. The stored design is then converted into the appropriate format (e.g., GDSII or CIF) for the fabrication of photolithographic masks, which typically include multiple copies of the chip design in question that are to be formed on a wafer or printed on a suitable substrate. The photolithographic masks are utilized to define areas of the wafer or printable electronic circuits (and/or the layers thereon) to be etched or otherwise processed or printed.

The resulting integrated circuit chips or printable electronic circuits can be distributed by the fabricator in raw wafer form (that is, as a single wafer that has multiple unpackaged chips), as a bare die, or in a packaged form or as individual printed circuits or in a sheet or roll of printed circuits. In the latter case the chip is mounted in a single chip package (such as a plastic carrier, with leads that are affixed to a motherboard or other higher level carrier) or in a multichip package (such as a ceramic carrier that has either or both surface interconnections or buried interconnections). In any case the chip might then be integrated with other chips, discrete circuit elements, and/or other signal processing devices as part of either (a) an intermediate product, such as a mother or daughter-board, or (b) an end product. The end product can be any product that includes integrated circuit chip or chips and/or printed circuits, ranging from toys and other low-end applications to advanced computer products having a display, a keyboard or other input device, and a central processor.

Harvesting ambient EM energy would transform a purely passive sensor into an autonomous sensor **110**a, **110**b, **111**c capable of periodic or sporadic sensor data acquisition, data logging and storage at times other than when being actively interrogated by a reader **160** as well as providing the necessary energy to either autonomously transmit a notable "sensor event", broadcast an alarm or "read me!" signal **460**, **485**, **490** when a threshold of the sensor **110**a, **110**b, **110**c has been exceeded or when a combination of various thresholds of the sensor **110**a, **110**b, **110**c have been exceeded.

The combination of passive and/or BAP and/or active wireless sensors **110**a, **110**b, **110**c having ambient EM energy harvesting capabilities and wireless communication capabilities as provided by the embodiments herein provide a new low cost means for remotely sensing the environment, monitoring the state of a home, buildings, structures, goods and devices as well as remote and local personal/patient monitoring, medical diagnostic and medical care solutions.

Cell phones, PDAs and PCs **170** are pervasive electronic devices that are already networked via the Internet. A combination or integration of RFID readers, WiFi technologies and/or cell phone technologies into a hybrid reader that transparently communicates with RFID sensor tags, the Internet and cell phone networks would facilitate the widespread deployment and usage of passive sensor tags equipped with EM energy harvesting technology.

Broadband wireless communications networks such as WiFi (including WiMax™ telecommunication equipment and WiBro™ telecommunication equipment and any combination of IEEE 802.1x (where x is used to convey any or all of the following: 1a, 1b, 1g, 5 or 6), IEEE 802.15.4 "Zigbee®" electronic devices, Bluetooth® telecommunication equipment, HomeRF® computer hardware/software, HiperLAN/1 and HiperLAN/2) are being widely deployed in offices, factories, warehouses, stores, homes, communities, and cities. With long read ranges (up to several hundred feet), RFID tags and RFID readers can benefit from aspects of the embodiments herein by: using RFID and/or WiFi for short range communication between a tag reader and wireless sensor tags; using the WiFi and/or the cellular network infrastructure to communicate the acquired sensor tag data over the Internet or cellular telephone networks (bi-directionally); and using WiFi routers/transceivers or cellular base stations as a source of ambient EM energy, with known frequency, that can be optimally harvested to provide energy to inexpensive passive (BAP and/or active tags with rechargeable energy sources) sensor tags.

Generally, the embodiments herein provide a technique for harvesting ambient RF EM energy for supplying, storing, recharging or supplementing the energy necessary to power active, BAP or passive wireless electronic devices, sensors and sensor networks, allowing them to become autonomous "data loggers" and/or empowering them to transmit their unique identification and sensor information when a sensed variable exceeds a threshold and triggers a vital "sensor event". The data gathered by these autonomous data loggers can also be transparently read at any time by a variety of reader technologies such as RFID readers, cell phones, personal data assistants, personal computers, WiFi, WiMax™telecommunication equipment and WiBro™ telecommunication equipment, including IEEE 802.1x (where x is used to convey any or all of the following: 1a, 1b, 1g, 5, and 6), "Zigbee®" electronic devices, Bluetooth® telecommunication equipment, HomeRF® computer hardware/software, HiperLAN/1and HiperLAN/2 and any hybrid combinations thereof. The embodiments herein also provide a hybrid RFID-WiFi reader/transceiver **340** and a hybrid RFID-WiFi-cell phone reader/transceiver **350**. The RFID reader module communicates with RFID tags, the WiFi module supplies ambient energy which the passive sensor tags are equipped to harvest and provides connectivity to the Internet and may also read WiFi sensor tags, and the cell phone module provides connectivity to cellular telephone networks.

The foregoing description of the specific embodiments will so fully reveal the general nature of the embodiments herein that others can, by applying current knowledge, readily modify and/or adapt for various applications such specific embodiments without departing from the generic concept, and, therefore, such adaptations and modifications should and are intended to be comprehended within the meaning and range of equivalents of the disclosed embodiments. It is to be understood that the phraseology or terminology employed herein is for the purpose of description and not of limitation. Therefore, while the embodiments herein have been described in terms of preferred embodiments, those skilled in the art will recognize that the embodiments herein can be practiced with modification within the spirit and scope of the appended claims.

What is claimed is:

1. An electronic device comprising:

a control module comprising an energy harvesting controller;

a tag module controlled by said control module;

a sensor module controlled by said control module;

an energy harvesting module controlled by said energy harvesting controller and adapted to wirelessly collect ambient radio frequency (RF) electromagnetic (EM) energy; and

a power module adapted to provide a power supply for said control module, said power supply being generated by the collected ambient RF EM energy,

wherein said energy harvesting controller is adapted to (i) assess power requirements of each of the tag and sensor modules, (ii) transfer power from said energy harvesting module to any of said tag and sensor modules, and (iii) charge a local energy storage device.

2. The electronic device of claim **1**, further comprising an antenna module shared by said energy harvesting module and said tag module.

3. The electronic device of claim **2**, wherein said antenna module comprises:

a rectification and impedance matching network;

at least one RF pad operatively connected to said rectification and impedance matching network; and

at least one antenna operatively connected to each of said at least one RF pad.

4. The electronic device of claim **1**, wherein said tag module comprises:

a memory component;

a RF communication interface operatively connected to said memory component;

at least one RF pad operatively connected to said RF communication interface; and

at least one antenna operatively connected to each of said at least one RF pad.

5. The electronic device of claim **1**, wherein said sensor module comprises:

a memory component;

a sensor interface and support sub-system operatively connected to said memory component;

at least one sensor pad operatively connected to said sensor interface and support sub-system; and

at least one antenna operatively connected to each of said at least one sensor pad.

6. The electronic device of claim **1**, wherein said sensor module comprises:

a memory component;

a sensor interface and support sub-system operatively connected to said memory component; and

at least one antenna operatively connected to sensor interface and support sub-system.

7. The electronic device of claim **1**, wherein said control module further comprises:

a radio frequency identification (RFID) tag controller; and

a sensor processing controller operatively connected to said RFID tag controller.

8. The electronic device of claim **1**, wherein said energy harvesting module comprises:

an energy harvesting interface and support sub-system;

at least one RF harvesting pad operatively connected to an energy harvesting interface and support sub-system; and

at least one antenna operatively connected to each of said at least one RF harvesting pad.

9. The electronic device of claim **1**, wherein said energy harvesting module comprises:

an energy harvesting interface and support sub-system;

at least one pair of RF harvesting pads operatively connected to said energy harvesting interface and support sub-system; and

at least one rectenna operatively connected to each of said at least one pair RF harvesting pads.

10. The electronic device of claim **9**, wherein said energy harvesting interface and support sub-system comprises:

a storage component;

a power conditioner component operatively connected to said storage component; and

a combiner operatively connected to said power conditioner.

11. The electronic device of claim **10**, wherein said energy harvesting interface and support sub-system comprises a rectification and impedance matching network operatively connected to said combiner.

12. The electronic device of claim **1**, wherein said power module comprises:

a power charger;

a power source operatively connected to said power charger; and

a voltage regulator operatively connected to said power source.

13. The electronic device of claim **1**, wherein said collected ambient RF EM energy enables said electronic device to be a fully autonomous data collector, alarm generator, event generator, data logger, and data processor independent of any other device.

14. The electronic device of claim **1**, wherein said power supply is generated only by said collected ambient RF EM energy.

15. A system comprising:

an ambient radio frequency (RF) electromagnetic (EM) energy source;

a sensor reader operatively connected to said ambient RF EM energy source; and

a sensor in communication with said sensor reader, said sensor comprising:

a control module comprising an energy harvesting controller;

a tag module controlled by said control module;

a sensor module controlled by said control module;

an energy harvesting module controlled by said energy harvesting controller and adapted to wirelessly collect said ambient RF EM energy; and

a power module adapted to provide a power supply for said control module, said power supply being generated by the collected ambient RF EM energy,

wherein said energy harvesting controller is adapted to (i) assess power requirements of each of the tag and sensor modules, (ii) transfer power from said energy harvesting module to any of said tag and sensor modules, and (iii) charge a local energy storage device.

16. The system of claim **15**, wherein said sensor further comprises an antenna module shared by said energy harvesting module and said tag module.

17. The system of claim **16**, wherein said antenna module comprises:

a rectification and impedance matching network;

at least one RF pad operatively connected to said rectification and impedance matching network; and

at least one antenna operatively connected to each of said at least one RF pad.

18. The system of claim **15**, wherein said tag module comprises:

a memory component;

a RF communication interface operatively connected to said memory component;

at least one RF pad operatively connected to said RF communication interface; and

at least one antenna operatively connected to each of said at least one RF pad.

19. The system of claim **15**, wherein said sensor module comprises:

a memory component;

a sensor interface and support sub-system operatively connected to said memory component;

at least one sensor pad operatively connected to said sensor interface and support sub-system; and

at least one antenna operatively connected to each of said at least one sensor pad.

20. The system of claim **15**, wherein said sensor module comprises:

a memory component;

a sensor interface and support sub-system operatively connected to said memory component; and

at least one antenna operatively connected to sensor interface and support sub-system.

21. The system of claim **15**, wherein said control module further comprises:

a radio frequency identification (RFID) tag controller; and

a sensor processing controller operatively connected to said RFID tag controller.

22. The system of claim **15**, wherein said energy harvesting module comprises:

an energy harvesting interface and support sub-system;

at least one RF harvesting pad operatively connected to an energy harvesting interface and support sub-system; and

at least one antenna operatively connected to each of said at least one RF harvesting pad.

23. The system of claim **15**, wherein said energy harvesting module comprises:

an energy harvesting interface and support sub-system;

at least one pair of RF harvesting pads operatively connected to said energy harvesting interface and support sub-system; and

at least one rectenna operatively connected to each of said at least one pair RF harvesting pads.

24. The system of claim **15**, wherein said energy harvesting interface and support sub-system comprises:

a storage component;

a power conditioner component operatively connected to said storage component; and

a combiner operatively connected to said power conditioner.

25. The system of claim **24**, wherein said energy harvesting interface and support sub-system comprises a rectification and impedance matching network operatively connected to said combiner.

26. The system of claim **15**, wherein said power module comprises:

a power charger;

a power source operatively connected to said power charger; and

a voltage regulator operatively connected to said power source.

27. The system of claim **15**, wherein said collected ambient RF EM energy enables said electronic device to be a fully autonomous data collector, alarm generator, event generator, data logger, and data processor independent of any other device.

28. The system of claim **15**, wherein said sensor reader comprises any of a cell phone, a personal display assistant (PDA), a personal computer (PC) reader, a radio frequency identification (RFID) reader, a broadband wireless fidelity (WiFi) device, and a combination thereof.

29. The system of claim **15**, wherein said power supply is generated only by said collected ambient RF EM energy.

30. The system of claim **15**, wherein said sensor is adapted to transmit a wireless signal to said sensor reader, and wherein said sensor reader is adapted to receive the transmitted wireless signal from said sensor.

31. The system of claim **15**, wherein said collected ambient RF EM energy facilitates transmission of said wireless signal when a selected sensor variable meets a predetermined threshold.

32. The system of claim **15**, wherein said ambient RF EM energy source comprises a wireless fidelity (WiFi) router adapted to allow said sensor reader to communicate over the Internet.

33. The system of claim **15**, wherein said ambient RF EM energy source comprises a hybrid wireless fidelity (WiFi) router transceiver adapted to allow said sensor reader to communicate over the Internet.

34. The system of claim **15**, wherein said sensor is a RF ambient EM energy harvesting sensor and is arranged with a plurality of other said sensors each adapted to collect data for climate control, security alarms, environmental alarms, and information gathering from other devices located within a communicable distance from said sensor, wherein all of said sensors are adapted to be any of locally and remotely monitored via any of the Internet and a cell phone network.

35. A device comprising:

a control module comprising:

an energy harvesting controller;

a radio frequency identification (RFID) tag controller operatively connected to said energy harvesting controller; and

a sensor processing controller operatively connected to said RFID tag controller;

a tag module controlled by said control module;

a sensor module controlled by said control module; and

an energy harvesting module directly connected to said control module and controlled by said energy harvesting controller, wherein said energy harvesting module is adapted to wirelessly collect, process, and store ambient radio frequency (RF) electromagnetic (EM) energy,

wherein said energy harvesting controller is adapted to (i) assess power requirements of each of the tag and sensor modules, (ii) transfer power from said energy harvesting module to any of said tag and sensor modules, and (iii) charge a local energy storage device, and

wherein power for operation of said control module, said tag module, said sensor module, and said energy harvesting module is generated only by the collected ambient RF EM energy.

(57) **ABSTRACT**

Examples described herein include systems and methods for multiband harvesting. An example system may include a single wideband antenna followed by several narrowband rectifier chains. Each rectifier chain may include a bandpass filter, a tuned impedance matching network, and a rectifier. The outputs of the rectifiers may be combined using a summation network. The summation network, which may be a diode summation network, may in some examples provide good performance even when only a subset o the narrowband harvesters (e.g. a subset of the rectifier chains) is excited.

CROSS-REFERENCE TO RELATED APPLICATION(S)

[0001] This application claims the benefit under 35 U.S.C. §119 of the earlier filing date of U.S. Provisional Application Ser. No. 62/144,114, filed Apr. 7, 2015, the entire contents of which are hereby incorporated by reference in their entirety for any purpose.

STATEMENT REGARDING RESEARCH & DEVELOPMENT

[0002] This invention was made with government support under CNS-1305072 awarded by the National Science Foundation. The government has certain rights in the invention.

TECHNICAL FIELD

[0003] Examples described herein relate generally to energy harvesting, and examples of wideband harvesters are described.

BACKGROUND

[0004] Harvesting ambient RF power is attractive as a means to operate microelectronics without wires, batteries, or even a dedicated RFID reader. However, previous ambient RF harvesters have been narrowband, making mobile sensing scenarios infeasible: for example, an RF harvester tuned to work in one city will not generally work in another, as the spectral environments tend to differ.

[0005] Ambient radio harvesting is a promising approach to powering battery-free sensing, computing, and communication devices. The vanishingly small amount of power now required by modern microelectronics, along with low power communication techniques, make ambient radio harvesting an increasingly viable power supply option. Compared to solar power, ambient RF has the advantage of being available at night, and is attractive from an industrial design perspective: the antennas already designed in to mobile devices for communication purposes can potentially become a power source, without requiring any changes to the form factor or appearance of the device.

[0006] However, there still exist challenges to widespread adoption of ambient RF harvesting as a power source. Conventional RF harvesting methods are only capable of extracting power from a narrow spectral band. The supply will cease to provide power when its particular source band is not available, either due to geographical fluctuations in spectral occupation, occlusion and shielding (e.g., from the walls of a building), or simply from multipath fading of the ambient signal. When starved of its energy source the device must cease to operate, limiting the application space mostly to a small geographical area with line-of-sight to an ambient radio source of interest.

[0007] Wideband harvesting may capture energy across a large swath of spectrum, but typically results in very low efficiency at any particular source frequency as the quality of the impedance match between the antenna and single rectifier reduces as the bandwidth increases. Tunable harvesting may allow a system to dynamically select a band of interest based on spectral availability, and therefore promises to be able to provide efficient rectification of signals from a single source, regardless of the frequency of that source. However, tunable harvesters in battery free systems may have difficulty bootstrapping to allow the system to coldstart, and also ignore energy outside the band to which they are tuned.

[0008] Existing multiband harvesting generally makes use of multiple antennas, each tuned to a band of interest, and each feeding an independent rectifier through a tuned matching circuit,

BRIEF DESCRIPTION OF THE DRAWINGS

[0009] FIG. **1** is a schematic illustration of a system arranged in accordance with examples described herein.

[0010] FIG. **2** is a schematic illustration of a circuitry branch arranged in accordance with examples described herein.

[0011] FIG. **3** is a schematic illustration of a switching network arranged in accordance with examples described herein.

[0012] FIG. **4** is a schematic illustration of a switching network arranged in accordance with examples described herein.

[0013] FIG. **5** is a schematic illustration of a switching network arranged in accordance with examples described herein.

[0014] FIG. **6** is a schematic illustration of a switching network arranged in accordance with examples described herein.

[0015] FIG. **7** is a flowchart illustrating a method for controlling a switching network with active switches arranged in accordance with examples described herein.

DETAILED DESCRIPTION

[0016] Certain details are set forth below to provide a sufficient understanding of embodiments of the invention. However, it will be clear to one skilled in the art that embodiments of the invention may be practiced without various of these particular details. In some instances, well-known circuits, control signals, timing protocols, signal processing elements or methods, and software operations have not been shown in detail in order to avoid unnecessarily obscuring the described embodiments of the invention.

[0017] Examples described herein include systems and methods for multiband harvesting. An example system may include as single wideband antenna followed by several narrowband rectifier chains. Each rectifier chain may include a bandpass filter, a tuned impedance matching network, and a rectifier. The outputs of the rectifiers may be combined using a summation network. The summation network, which may be a diode summation network, may in some examples provide good performance even when only a subset of the narrowband harvesters (e.g., a subset of the rectifier chains) is excited.

[0018] FIG. **1** is a schematic illustration of a system **100** arranged in accordance with examples described herein. The system **100** includes an antenna **102**, trunk node **104**, circuitry branch **106**, circuitry branch **108**, circuitry branch **110**, circuitry branch **112**, switching network **114**, and output **116**. Each of the circuitry branches includes a respective bandpass filter, respective matching network, and respective rectifier. The antenna **102**, which may be a wideband antenna, is coupled to the trunk node **104**, which in turn is coupled to each of the circuitry branches **106-112**. The circuitry branches **106-112** are coupled to the switching network **114** to sum selected outputs of the circuitry branches and provide a DC voltage at the output **116**,

[0019] The antenna **102** may be a wideband antenna. Generally, the wideband antenna may receive RF signals over a frequency band which is wider than each of the frequency bands filtered by the bandpass filters in the circuitry branches in the system (e.g., circuitry branches **106-112**). Generally, a wideband antenna used to implement the antenna **102** may have approximately the same operating characteristics over the passband of the antenna **102**. The antenna **102** may have a passband that includes frequency bands of interest for energy harvesting (e.g. frequency bands that may be present in an environment where energy harvesting is to be performed) including, but not limited to, cellular frequencies, TV frequencies, and Wi-Fi frequencies. Accordingly, the antenna **102** may receive wireless signals from multiple signal sources, each type of signal source generally configured to transmit wireless signals in a different frequency hand (e,g, short-range transmission. TV broadcast, Wi-Fi transmission). Any signal source may generally be used to harvest energy in accordance with examples described herein, including short-range transmitters (e.g. RFID readers), TV broadcasters, Wi-fi routers, communication devices, and combinations thereof.

[0020] Four circuitry branches are shown in FIG. **1**, however any number of frequency branches may be used in other examples. In some examples, two frequency branches may be used. In some examples, three, four, five, six, seven, eight, nine, or ten frequency branches may be used. Generally, each frequency branch may include a respective bandpass filter configured to pass a particular frequency hand. The frequency hand passed by the respective bandpass filters are each generally narrower than the passband of the antenna **102**. Each (in some examples, at least two) of the respective bandpass filters may he configured to pass a different frequency band. The respective bandpass filters may be orthogonally tuned. The frequency band filtered by the bandpass filter may generally be referred to by specifying its center frequency (e.g. 433 MHz, 915 MHz, 2.45 GHz, in some examples). Examples of frequency bands which may be filtered by the bandpass filters include 433 MHz, 915 MHz, 2.45 GHz in some examples. A range of 400-900 MHz in specified intervals in some examples. Generally, any number and selection of frequencies may be passed, including those in mobile communication. TV, or other bands.

[0021] Each circuitry branch further includes a matching network coupled to the bandpass filter. The matching network may be configured to provide impedance matching for the respective circuitry branch to the respective rectifier in the branch. Each matching network may have one or more resistive elements (e,g, resistors), capacitive elements (e.g. capacitors), and/or inductive elements (e.g. inductors) that provide the impedance.

[0022] Each circuitry branch further includes a respective rectifier. The rectifier is configured to receive the RF signal provided from the matching network and rectify the signal to provide a DC signal. The respective rectifiers may be implemented using respective M stage Dickson charge pumps, which may provide, rectification and voltage amplification in sonic examples,

[0023] Accordingly, each circuitry branch coupled to the antenna **102** (e.g. at the trunk node **104**) may pass a respective frequency band to a matching network and provide the resulting signal to a rectifier. The trunk node **104** may be implemented as a port for the antenna **102**. Multiple rectified signals may be provided, each from a different frequency band. Recall the different frequency bands may correspond to signals received from different environmental frequency sources (e.g., cellular, TV, Wi-Fi).

[0024] The multiple rectified signals may be combined at an output **116**. In some examples, a serial combination (e.g. sum) of the rectified signals is provided, at the output **116**. The output **116** may provide a DC signal (e.g., a DC voltage). The output **116** DC signal may be used to power one or more load circuits (e.g., sensors). Accordingly, the system **100** may be used to harvest energy from many different frequency bands in an environment using a single antenna in some examples.

[0025] Generally, the system **100** may have a number (N) of bandpass filters, and the respective bands may be spaced by frequency deltas (ΔF), and each rectifier may have a respective number of stages.

[0026] Generally, any frequency bands may be selected for the multiband harvester system **100** of FIG. **1**. For example, the system **100** may implement a multi-protocol arrangement targeting several commonly used bands. Each circuitry branch may be designed to filter a particular band. For instance, 433 MHz, 915 MHz, and 2.45 GHz could be filtered by the circuitry branches **106**, **108**, and **110**, respectively. Other frequencies may be used in other examples. Accordingly, knowledge of commonly occupied portions of the spectrum which will be most likely to yield power may be used to select properties of the circuitry branches. This method may achieve high practical efficiency with low complexity, as the number of target bands may be relatively small.

[0027] In some examples, each bandpass tiller may filter a band a set distance from the neighboring bands over a wide bandwidth (e.g. 400-900 MHz in some examples). Accordingly, any number and placement of RF signals may be efficiently harvested in some examples. Accordingly, the energy harvester may capture energy efficiently at nearly any frequency in a larger prescribed bandwidth (e.g., 400-900 MHz in some examples). By allocating circuitry branches for filtering across a complete range, design of the system **100** may not rely on knowledge of commonly occupied bands in some examples, or on current details of regulatory spectral allocation.

[0028] Examples of parallel harvester topologies, such as that shown in FIG. **1**, may provide a good match to one single-port antenna (e.g. Antenna **102**) at multiple bands, at least because a respective matching network may be used for each band. This is in contrast to solutions which may make use of multiple antennas, each covering a particular band of interest, or make use of dual-band antennas with multiple ports and a single rectifier. Therefore, in contrast to existing work, systems described herein may more easily scale in some examples to a large number of frequency bands with no additional antennas or antenna ports required in some examples.

[0029] The bandpass filters and matching networks used in the various circuitry branches may in some examples be tuned for desired performance. Tuning may generally refer to selecting and/or adjusting the parameters (e.g. values) of the various circuit components used m the circuitry branches, including the bandpass filters and the matching networks. In some examples, a cost function is used to optimize the design of the circuitry branches. An example cost function includes minimizing reflected energy in matching the antenna **102** to the trunk node **104** of the circuitry branches. For example, the sum of the return losses (e.g. S11) of the harvester at each frequency band should be minimized. An example cost function may additionally tit instead include minimizing impact of adjacent circuitry branches on impedance of the network at each bandpass frequency of interest. For example, for each center frequency, the impedance of adjacent bands may be maximized,

[0030] In some examples, minimizing a weighted combination of the two above-described cost function factors may be used to select the bandpass filter and match network values for each band of the harvester. For example, overall S11 at each design frequency may be minimized while maximizing adjacent band impedance. For example, considering, a scenario in which only a single continuous wave is presented to the multiband harvester. If overall S11 is simply minimized, the power of this continuous wave may end up distributed over several consecutive rectifiers, resulting in several very poorly excited rectifiers and therefore may be an inefficient system. To also minimize the match quality of adjacent bands generally means that, instead of distributing this continuous wave's power, this power may be focused on one rectifier and thereby maximize or improve the efficiency of the system in harvesting that continuous wave signal. Since most ambient or intentionally radiated signals may be relatively narrow bandwidth compared to the overall scope of the system **100**, most sources may excite only one of the circuitry branches of the harvester and therefore support this optimization strategy. Other optimization strategies may be used in other examples.

[0031] To perform optimization, in some examples, as lumped element model of the harvester may be developed, for example in MATLAB. The model may make use of empirical rectifier impedance measurements taken from implementations of the system **100** in some examples. Each rectifier in the multiband harvester may be characterized at each of the design frequencies (e.g. center frequencies for each of the circuitry branches) in order to achieve a more realistic model of the harvester. A simplifying model of the antenna may be used in which impedance is constant (e.g. 50Ω) across the entire hand of interest, hi some examples, the antenna impedance may be measured across the operating bandwidth and used to better tune the system **100**.

[0032] Approximations for the bandpass filter matching network values for each band may be forward-computed in some examples by assuming each band is independent and selecting the values which minimize S11. The resulting values may be used as the seed values for an optimizing search based on cost functions described herein. The resulting component values would be bandpass and matching network component values which minimize overall S11 at each design frequency while minimizing interaction between adjacent bands.

[0033] Distributed modeling may be used for multiband harvesters with a large band count, which may significantly increase the complexity of modeling, and the difficulty of tuning the harvester.

[0034] In some examples, the system **100** may overcome the Bode-Fano limit, for example, by allowing the match to effectively be distributed across multiple loads. Generally, the Bode-Fano theorem describes the limits of impedance matching between a source and complex load. In conventional single-band RF harvesters or wideband harvesters, the bandwidth over which the antenna can be well matched to a single rectifier will be limited, therefore placing, an upper limit on the site of the hand over which the RF-DC conversion will remain efficient. By allowing the match to be distributed across multiple loads (e.g. multiple circuitry branches), the system **100** may in some examples overcome this limit and achieve improved efficiency over a larger band.

[0035] Note there are at least two impedance interfaces in the system **100** that may be matched to improve efficiency of RF-DC conversion. The first is the interface between the antenna **102** and the trunk node **104** of the multiband harvester. The second is the interface between the trunk node **104** and the rectifier for each of the branches. The Bode-Fano theorem may only place a limit on match bandwidth for complex sources and/or loads. It may model the limitations of the match between the trunk node **104** and the rectifier for each branch, since the rectifier impedance will generally always be complex. However, the antenna-to-trunk interface may be designed such that the impedance looking into each bandpass filter at its resonant frequency may be real and matched to the antenna. Because the adjacent branch bandpass filters may have negligible admittance at any given frequency, they may not contribute significantly to the impedance viewed from the trunk node **104** at adjacent hands. Accordingly, each circuitry branch of the system **100** may be Bode-Fano-constrained, but the antenna-to-trunk match (and therefore the system **100** as a whole) may not be so constrained.

[0036] FIG. **2** is a schematic illustration of a circuitry branch arranged in accordance with examples described herein. The circuitry branch **208** may include trunk node **202**, bandpass filter **204**, matching network **206**, and rectifier **210**. The circuitry branch **208** may be used to implement any of the circuitry branches described herein, including any of those shown in FIG. **1**, for example.

[0037] The circuitry branch **208** includes a trunk node **202**, which may be coupled to an antenna, such as the antenna **102** of FIG. **1**. The circuitry branch **208** may include a bandpass filter **204** coupled to the trunk node **202**. The bandpass filter **204** may filter a particular frequency band, and may include one or more capacitive elements (e.g. capacitors), inductive elements (e.g. inductors), and/or resistive elements (e.g. resistors) selected to filter for the particular frequency band. As shown in FIG. **2**, the bandpass filter **204** includes a capacitor in series with an inductor.

[0038] The bandpass filter **204** is coupled to a matching network **206**. The matching network **206** may include one or more capacitive elements (e.g. capacitors), inductive elements (e.g. inductors), and/or resistive elements (e.g. resistors) selected to match the circuitry branch **208** to the rectifier **210**. For example, the matching network **206** as shown in FIG. **2** includes a capacitor coupled between an output of the bandpass filter **204** and ground, and an inductor coupled between the output of the bandpass filter **204** and an input of the rectifier **210**.

[0039] The rectifier **210** may be implemented using circuitry for rectifying and/or providing voltage amplification. As shown in FIG. **2**, the rectifier **210** may be implemented using an M stage Dickson charge pump.

[0040] As described herein, for example, with reference to FIG. **1**, multiple circuitry branches may be used in systems described herein, and indicated by 'next band' and 'previous band' in FIG. **2**. To sum voltages provided by the rectifiers in each circuitry branch, the outputs of the rectifiers may be connected in series in some examples. In other examples, a parallel combination may be used.

[0041] Accordingly, systems described herein may use a serial connection between independent rectifiers, a topology which, in the context of multiband harvesting, may only provide high efficiency in the case where all bands (e.g. circuitry branches) are excited. If one or more bands in such a serially connected system are not excited, the diode drops in the unexcited bands' charge pumps may need to be overcome by the other bands, resulting in efficiency degradation. For example, unexcited bands' RF-DC conversion diodes may cease to be a source of voltage (e.g. produce an output voltage below a threshold, or no output voltage) at low or zero excitation power (e.g. received power below a threshold) and provide or develop a voltage drop, therefore impeding the flow of current from serially connected excited bands. Summation topologies which improve and/or overcome this effect generally allow current to divert around unexcited bands by providing a path of lesser resistance. Inactive bands accordingly may be shorted using a switching network.

[0042] It is generally difficult to produce semiconductor switches which are normally-closed when no supply voltage is present, a harvester which is capable of cold-starting (starting with all circuit nodes at zero volts) generally may not have normally-closed connections. However, when rectifiers from multiple circuitry branches, as described herein, are connected serially, normally-open switches can be used to short inactive bands and may also behave as open switches during a cold-start. Examples of switching networks described herein may accordingly include normally-open switches to facilitate cold-start of the system.

[0043] The presence of unexcited bands (e.g. circuitry branches) may commonly occur in some examples, for instance where each circuitry branch may be designed to filter and rectify RF signals from a particular type of signal source (e.g. short-range, cellular, TV, Wi-Fi). Those bands may not all always be occupied by signals in the environment. Accordingly, during operation, it may commonly occur that one or more circuitry branches of systems described herein may not be excited at any given time.

[0044] Accordingly, in sonic examples, a switching network may be provided (e.g. the switching network **114** of FIG. **1**), to disconnect certain rectifiers from the output **116**, particularly when the rectifiers are not excited, and would otherwise provide disadvantageous diode drops in a serially-connected output.

[0045] In some examples, the switching network may be implemented using "shortcut" diodes to bypass the circuitry branches which are not active, allowing an automatic optimal configuration to be achieved in summing the voltages produced by each band rectifier. These shortcut diodes my advantageously have both low threshold and low leakage in some examples, attributes which may be achievable as they will be operating at DC.

[0046] In some examples, "dead weight" diodes associated with un-excited circuitry branches may be bypassed with a single, low threshold, low leakage DC diode. Such topology may reduce any extra overhead of unexcited bands, but may still have overhead in some examples if there are many unexcited hands with many bypass diodes for current to traverse.

[0047] FIG. **3** is a schematic illustration of a switching network arranged in accordance with examples described herein. The switching network **300** shown in FIG. **3** is for use with five serially-connected circuitry branches, but any number of circuitry branches may be used. The circuitry branches are represented in FIG. **3** by their rectifiers—rectifier **302**, rectifier **304**, rectifier **306**, rectifier **308**, and rectifier **310**. The switches in the switching network **300** are implemented using diodes. Other switching elements may be used in other examples, including reversible fuses.

[0048] In the example of FIG. **3**, one diode is provided for each circuitry branch to provide a bypass path for current when the rectifier is not producing sufficient voltage. Each diode is accordingly connected across one or more output diodes of the rectifier to provide a bypass path around the output diodes. For example, each diode may be connected form an output of a previous band rectifier to the output of the next band rectifier.

[0049] As shown, the diode **320** is connected between ground and an output of rectifier **310**. Diode **318** is connected between an output of rectifier **310** and an output of rectifier **308**. Diode **316** is connected between an output of rectifier **308** and an output of rectifier **306**. Diode **314** is connected between an output of rectifier **306** and rectifier **304**. Diode **312** is connected between an output of rectifier **304** and output **322**, the output node of the overall system providing voltage V_{sum}.

[0050] When any of the rectifiers **302**-**310** are providing insufficient voltage to maintain the respective diode in an open state, the respective diode will provide a lower resistance current path, bypassing the output diodes of the rectifier, and avoiding presenting the diode drops associated with those output diodes to the output voltage V_{sum}. Other example switching networks may be able to reduce a number of bypass diodes used when multiple circuitry branches are unexcited. In FIG. **3**, generally one bypass diode was used per unexcited circuitry branch.

[0051] A voltage drop associated with bypass diodes in use, may however adversely affect the output voltage V_{sum}.

[0052] In some examples, "shortcut" diodes may be placed between each serially-connected band output and the two output rails (e.g. the output and ground). This may reduce the efficiency hit caused by the bypass diodes i, but may not achieve optimal power combination in all cases. For instance, if the first and second bands are excited the output voltage may be near their sum (minus diode drops), but if the first and third bands are excited the output voltage may be as low as the maximum of the two band outputs, effectively throwing away the benefit of the second excited band.

[0053] FIG. **4** is a schematic illustration of as switching network arranged in accordance with examples described herein. The switching, network **400** is shown for use with three circuitry branches (e.g. bands), however in other examples switching networks may be provided for other numbers of circuitry branches, including the four circuitry branch example of FIG. **1**. In FIG. **4**, each circuitry branch is represented by their respective rectifier—rectifier **404**, rectifier **406**, and rectifier **408**.

[0054] The example of FIG. **4** may allow the output **402** to attain the sum voltage of all excited bands, regardless of whether the excited bands are contiguous or scattered throughout the harvester array. As shown in FIG. **4**, each node in the rectifier stack is connected to every other node with a diode, generally a properly oriented, low threshold and low leakage DC diode.

[0055] For example, the output of rectifier **408** is connected to the output of the rectifier **406** by diode **412**, to output **402** by diode **416**, and to ground by diode **414**. The output of rectifier **406** is connected to the output **402** by diode **410** and to ground by diode **418**.

[0056] If only rectifier **408** is not excited (e.g. insufficient energy has been rectified by the circuitry branch, such that voltage at an output of the rectifier is below a threshold) while rectifiers **406** and **404** are excited, the voltage at the output of the rectifier **408** may be such that diode **414** becomes a short, while the voltages at the outputs of rectifier **406** and rectifier **404** are such that the diodes **412** and **410** are open. In this manner, the output **402** may be a sum of the voltages provided by the rectifier **406** and rectifier **404**, minus a voltage drop provided by the bypass diode **414**. In this manner, the rectifier **408** has been disconnected from the output **402** by diode **414**.

[0057] If rectifier **406** is not excited while rectifier **404** and rectifier **408** are excited, the voltage across diode **412** may cause diode **412** to short, disconnecting the rectifier **406** from the output **402**. However, the voltages at the outputs of the rectifier **408** and the rectifier **404** are such that the diodes **410** and **414** are open. In this manner, the rectifier **406** has been disconnected from the output **402** and the output **402** may provide a voltage equal to the sum of the outputs of rectifier **404** and rectifier **408** less the voltage drop provided by diode **412**.

[0058] If rectifier **404** is not excited while rectifier **406** and rectifier **408** are excited, the voltage across diode **410** may cause diode **410** to short, disconnecting the diode **410** from the output **402**. However, the voltages at the outputs of the rectifier **406** and the rectifier **408** are such that the diodes **412** and **414** are open. In this manner, the rectifier **404** has been disconnected form the output **402** and the output **402** may provide a voltage equal to the sum of the outputs of rectifier **408** and rectifier **406**, less the voltage drop provided by diode **410**.

[0059] If both rectifier **408** and rectifier **406** are not excited while rectifier **404** is excited, the voltage across diode **418** may be such that diode **418** is considered a short, effectively disconnecting the rectifier **408** and the rectifier **406** from the output **402**. The voltage at the output **402** may be the voltage provided by the rectifier **404** less the voltage drop of the diode **418**.

[0060] If both rectifier **404** and rectifier **406** are not excited while rectifier **408** is excited, the voltage across diode **416** may be such that diode **416** is considered a short, effectively disconnecting the rectifier **404** and rectifier **406** from the output **402**. The voltage at the output **402** may be the voltage provided by the rectifier **408** less the voltage drop of the diode **416**.

[0061] If both rectifier **408** and rectifier **404** are not excited while rectifier **406** is excited, the voltages across diode **410** and diode **414** may be such that diode **410** and diode **414** are considered shorts, but the diode **412** is open, disconnecting the rectifier **408** and rectifier **404** from the output **402**. The voltage at the output **402** may be the voltage provided by the rectifier **406** less the voltage drop of the diode **410** and diode **414**.

[0062] Accordingly, the output **402** in the example of FIG. **4** may be a sum total of voltages provided by rectifiers in all excited circuitry branches, minus some number of diode drops which depends on the number and arrangement of bands excited. When multiple bands are not excited, they may be in some cases bypassed with a fewer number of diodes than the number of excited bands (e.g. one diode **418** may be used to bypass rectifier **408** and rectifier **406**). In situations when all hands are excited, the matching network of FIG. **4** may perform equivalently or nearly equivalently to the approach of simple serial combination of bands. When only select bands are excited and others left unexcited, the matching network of FIG. **4** may perform more efficiently than the simple serial approach.

[0063] The leakage current of so many DC shortcut diodes may be considered when implementing a multiband harvester with a large number of bands. However, while the total number of DC shortcut diodes in the system can grow large as the number of bands increases, the leakage may not scale quite as geometrically, as the average of the reverse voltage across a diode in the system will decrease as the number of hands increases (given some number and arrangement of excited bands).

[0064] FIG. **5** is a schematic illustration of a switching network arranged in accordance with examples described herein. The strategy used for the switching network **500** of FIG. **5** is similar to that used in FIG. **4**, however the switching network **500** of FIG. **5** is shown with five circuitry branches—represented by rectifier **502**, rectifier **504**, rectifier **506**, rectifier **508**, and rectifier **510**.

[0065] The output of each rectifier is connected to the output of every other rectifier in the serially chain with a diode. Accordingly, a total of 14 diodes are used in FIG. **5**. A single diode may be used to bypass any number of neighboring rectifiers (e.g. disconnect the rectifiers from the output **512**). For example, a single diode may be used to bypass rectifier **510**, rectifier **508**, rectifier **506**, and rectifier **504** when those corresponding circuitry branches are all unexcited, and only the circuitry branch associated with rectifier **502** is excited.

[0066] FIG. **6** is a schematic illustration of a switching network arranged in accordance with examples described herein. The switching network **600** is shown for use with a system having five circuitry branches, represented in FIG. **6** by their rectifiers—rectifier **602**, rectifier **604**, rectifier **606**, rectifier **608**, and rectifier **610**. In the example of FIG. **6**, active switches are used to bypass un-excited circuitry branches (e.g. disconnect the rectifiers of the unexcited branches from the output).

[0067] The active switch **612** is provided to bypass rectifier **602** and is connected between the output of rectifier **604** and output **622** of the system. The active switch **614** is provided to bypass rectifier **604** and is connected between the output of rectifier **606** and the output of rectifier **604**. The active switch **616** is provided, to bypass rectifier **606** and is connected between the output of rectifier **608** and the output of rectifier **606**. The active switch **618** is provided to bypass rectifier **608** and is connected between the output of rectifier **610** and the output of rectifier **608**. The active switch **620** is provided to bypass rectifier **610** and is connected between ground and an output of rectifier **610**.

[0068] The active switches used in examples described herein may be implemented using a variety of components, including but not limited to transistors and reversible fuses.

[0069] Generally, the active switches each have a control terminal for receipt of a respective control signal, and may close responsive to receipt of an active control signal. In some examples, however, normally closed switches may additionally or instead be used.

[0070] A diode switching network may be present in some examples together with a network of active switches. For example, the switching network **500** of FIG. **5** may be connected in parallel with the switching network **600** of FIG. **6**. In that manner, the diode switching network may be used during cold-start of a system—e.g. when a system is in a startup mode. During cold-start or a start-up mode, it may be undesirable or impractical to control active switches, however passive diodes may supply the bypass functionality described herein. Once startup is achieved and active control is possible (e.g. during normal operation), the bypass functionality may be performed using the active switches.

[0071] FIG. **7** is a flowchart illustrating to method for controlling a switching network with active switches arranged in accordance with examples described herein. The method **700** may be perforated by as controller, logic circuitry, or other computing system provided for control of switching networks including active switches described herein. The method **700** may be implemented in hardware, software, firmware, or combinations thereof.

[0072] The method **700** may begin with a reset or cold start of a system in block **702**. For example, when a system (e.g. the system in any of the Figures shown herein) first receives power or first receives power after a period of time has elapsed without power, it may be in a startup mode (e.g. cold start). In some examples, where a complete or partial passive switching network is present (e,g, using diodes), the diodes may be used to bypass unexcited circuitry branches (e.g. disconnect their rectifiers from an output node).

[0073] In decision block **704**, a determination is made whether the system has sufficient energy for optimization. The controller, logic circuitry, or other computing system implementing the method may monitor available energy, e.g. by monitoring an output voltage, energy stored on a capacitor, or other indicia of available energy. The energy reservoir being monitored may be connected, for example, after voltages from rectifiers in multiple circuitry branches have been summed, for example after a switching network (e.g. after switching network **114** of FIG. **1**). If the available energy is above a threshold for optimization, then the method may proceed. If not, the method may end, or may move to consider a next switch in the system (e.g. Block **714**).

[0074] If there is sufficient energy for optimization, a state of one active switch in the system may be changed in block **706**. Following the change, the outwit voltage of the system may be monitored. Referring to FIG. **6** for example, the active switch **620** may be changed from an open to a closed state, and the output **622** may be monitored. If the output **622** improves (e.g. a greater amount of voltage is available after changing the state of the active switch **620**), the new state may be adopted in block **710**. If the output **622** does not improve (e,g, a same or lesser amount of voltage is available after changing the state of active switch **620**), the controller logic circuitry, or other computing system performing the method **700** may revert the active switch **620** to the prior state (e.g. open).

[0075] In block **714**, the method is repeated for a next switch in the system. For example, an energy check may be performed to confirm sufficient energy for optimization, the switch state may be changed and the output voltage monitored, as described in blocks **704**, **706**, **708**, **710**, and **712**. These blocks may be repeated for each active switch in the switching network (e.g. each active switch shown in FIG. **6**). Once all switches have been considered, in some examples, the system will repeat the process again for all switches. In this manner the state of all switches may be considered continuously during operation of the system. In some examples, once all switches have been considered, the control system may enter a sleep state and perform optimization only from time to time after the first optimization, or not until another reset or cold start in some examples.

[0076] Examples described herein may provide RF energy harvesting which may be suitable for mobile applications (e.g. to power a cell phone, other mobile computing system, and/or sensors). Example energy harvesters described, herein may be used to power ambient RF-powered data logging sensors that may, for example, upload data to RFID readers when in range.

[0077] An integrated multiband system with a single antenna port may be used as a universal RF energy harvesting solution. Systems may be able to be used in a plug-n-play fashion with a wide variety of antennas and across a wide variety of target frequencies.

[0078] Examples of systems (e.g. harvesters) described, herein may provide benefits in some examples. Example benefits are described herein to facilitate understanding. It is to be understood that not all examples may have all, or even any of the described benefits. Some example benefits may include (1) RF source flexibility (2) access to additional power and/or (3) improved sensitivity. RF source flexibility generally refers to the harvester being able to operate using any subset of several potential source frequencies. The benefit of multiband harvesting generally provides access to additional power because the harvester can collect energy from multiple RF sources simultaneously. Another benefit may be that multiband harvesting can provide improved sensitivity in circumstances in which no one source provides enough power to operate the device, but several sources in combination do.

[0079] RF source flexibility may be significant because it may enable mobile RF harvesting: the frequency of the strongest RF source may not generally be the same in each city; examples of multiband harvesters described herein may allow as device to capture power from the strongest sources it encounters in the environment. The summation networks described herein may be advantageous for RF source flexibility. A multiband harvester without the switching networks may require simultaneous excitation in all or most of its input hands. While such a harvester might provide benefits such as increased total power and increased sensitivity, it would not provide RF source flexibility. One can imagine providing RF source flexibility with an actively tunable harvester design, but the active circuitry would typically cost substantial power, resulting, in a system with low net efficiency.

[0080] The efficient multiband harvesting described, herein can enable mobile RF harvesting, increasing the practicality of ambient RF as a power source. Applied in the context of RFID, this can enable a sensor tag that uses ambient RF power to sense and to data, and then downloads the data when interrogated by an RFID reader.

[0081] Example energy harvesting systems described herein may be utilized in a backscattering transponder. Such a device may operate both as a passive RFID tag and as an ambient backscatter transponder, capable of operating from both "planted" energy sourced by an RFID reader, and with "wild" RF energy from existing signals such as those used in Wi-Fi, cellular, and TV transmissions. Such a backscattering transponder could communicate orthogonally at each of the design frequencies of the multiband harvester by performing impedance modulation separately for each band, and may be able to achieve communication diversity and multiplexing gains which could result in higher rates, longer ranges, and improved robustness.

[0082] Example energy harvesting systems described herein may be utilized in stand-alone sensor devices—e.g. Internet-of-things devices. Sensor devices that may utilize energy harvesting systems described herein include, but are not limited to, home sensors where energy harvesting systems described herein may eliminate or reduce a need to change the home sensor batteries.

[0083] Example energy harvesting systems described herein may be utilized in existing devices to provide additional functionality without depleting traditional power sources. For example, energy harvesting systems described herein may be utilized on a cell phone, tablet, laptop, or other device to provide minimum functionality when the battery is depleted (e.g. for use in locating the device and/or providing 'always on' for faster wake-up of the device, and/or maintaining state of the device).

[0084] Example harvesting systems described herein (e.g. circuitry branches and switching networks) may be implemented as a system on a chip or multiple chips in some examples). The chip may have a port for connection to an antenna (e.g. a wideband antenna). Example devices (e.g. cell phones, tablets, appliances, sensors, backscattering transponders) may include such an example chip and use it to harvest energy from the environment and power one or more functionalities of the device.

EXAMPLES

[0085] A SPICE model of a multiband harvester was constructed and subjected to some virtual experimentation. First, a single band model was constructed using Avago HSMS-285C diode models in a 3-stage Dickson charge pump arrangement. The impedance of the single band charge pump was measured at each of the design frequencies for the system. Eight bands in the region of the spectrum were selected: 300 MHz, 356 MHz, 423 MHz, 503 MHz, 597 MHz, 709 MHz, 842 MHz, and 1 GHz. A first order LC bandpass fiber was generated at each design frequency (with a Q of 5) and used to isolate the eight bands. A low-pass L-match network was then constructed for each band, to match the 50Ω source to the load impedance of each band's rectifier at its design frequency. All values were forward-computed based on initial simulated impedance measurements; no iteration was performed once initial component values had been selected,

[0086] A diode summation network was also constructed using the SPICE model for the SDM03U40 Schottky diode manufactured by Diodes. Inc., and used to stun the DC output power from each of the eight bands. The output of the summation network was connected to a 100 kΩ load resistor to simulate a device being powered.

[0087] The RF-DC Version efficiency as a function of frequency tier a single-tone excitation indicated the intended design frequencies aligned well with the conversion efficiency peaks, though there was variation in the conversion efficiency between bands.

[0088] To characterize the effectiveness of the summation network and its impact on the multiband harvester, a series of tests were done on two systems: One with the summation network in place, and one with only a simple serial connection between bands. The two systems were otherwise identical. Eight simulated voltage sources were connected serially to generate up to eight excitation tones. The eight sources were modulated in a binary-weighted fashion, turning on or off each source to ultimately produce every possible combination of excited bands (eight bands yields 256 permutations). The source power per band was set to +3 dBm for this simulation. A transient simulation was performed for each combination of excited bands, and the summed output voltage was measured after a fixed stabilization period had expired.

[0089] Power from multiple bands combined somewhat linearly, with each additional hand contributing approximately 750 μW to the sum output power on average. Note that for each permutation of excited bands, the output power may vary for two reasons: The first is that the RF-DC conversion efficiency for each band may not be equal. The second is more subtle; the diode summation network may exhibit a different operating efficiency depending on the arrangement (not simply the number) of excited bands.

[0090] This arrangement-dependent summation efficiency can be shown by comparing the case in which only bands **1**, **3**, and **5** are excited to the case in which only bands **1**, **2**, and **3** are excited. In the former case, multiple shortcut diode drops must be overcome between the excited bands, while in the latter case the bands are adjacent and therefore sum serially with no diode drop between them.

[0091] On average the summation network provided a significant benefit in terms of delivered power), though there are a number of test eases in which the presence of the summation network reduces overall efficiency. This may be attributed to the reverse leakage current of the summation diodes, which may become a significant factor with the large number of diodes required to implement the network.

[0092] A 2-band and 5-band prototype were implemented with discrete components. The prototypes use 3 stages per band and the described "shortcut" summation topology, and were connected to a wideband log-periodic antenna with a roughly 6 dBi gain when the experiment required. The two-band harvester design frequencies are 539 MHz and 915 MHz, and the fiveband harvester design frequencies are 400 MHz, 480 MHz, 590 MHz, 735 MHz, and 900 MHz. Avago HSMS-285C Schottky; diodes were used in the 3-stage RF-DC conversion charge pumps. The summation network made use of low-threshold and low-leakage SDM03U40 diodes manufactured by Diodes, Inc.

[0093] Tuning of the prototypes were accomplished by first installing the bandpass filters for every band, shorting the L-match network for every band, and measuring RF port impedance at each of the design frequencies with a test power of −10 dBm. The impedance measurements made with the shorted matching network were used to estimate matching component values. Matching was then done empirically for each and in turn, with some iteration due to the impact of each band on the consecutive bands.

[0094] During the following tests to characterize the performance of the harvester. A 100 kΩ resistive load was placed at the output of the summation network.

[0095] A. Single-Tone Response

[0096] The 2-band and 5-band prototypes were first subjected to a single-tone excitation at a power level of −10 dBm (100 μW), and the S11 (reflected power) and RF-DC conversion efficiency were measured.

[0097] During the tuning procedure, the minimization of S11 was the only goal, and this was a potential cause for the decreased efficiency observed in the 5-band harvester: In this system, S11 was not a good predictor for RFDC conversion efficiency. While the minimal S11 and maximal RF-DC efficiency points for the 2-band prototype matched well, the 5-hand harvester did not exhibit the same correlation for every band. For instance, while the fourth band's S11 showed a very good impedance match to the 50Ω source, the RFDC conversion efficiency was extremely poor compared to the other hands. The discrepancy between S11 and RF-DC, efficiency in the 5-band prototype may be due to the large amount of interaction between bands; in that prototype the quality factor of the bandpass filter was low and therefore adjacent hands may have had a strong interaction.

[0098] An experiment was performed to characterize the multi-band excitation response of the 2-band prototype. The goal of this experiment was to quantify how well the harvester can combine power from multiple hands.

[0099] B. Multi-Excitation Response

[0100] The multi-excitation experiment consisted of a two-hand excitation produced by combining the output of two RF function generators. The RF-DC conversion efficiency of the entire system increased as more hands were excited.

[0101] C. In the Wild

[0102] The 5-band harvester was subjected to two scenarios in which "wild" RF energy was present. In the first scenario, it was placed in the field of a UHF RFID reader emitting 30 dBm at 915 MHz into a 6 dBic circularly polarized antenna. At a distance of 5 m from the RFID reader, the harvester was able to produce 2.3 V across a 100 kΩ load, for a delivered power of 53 μW.

[0103] In the second scenario, the 5-hand harvester was placed at a location 4.2 km distant from a TV broadcast tower emitting 1 MW at 539 MHz, and was able to produce 2.5 V across the same 100 kΩ load for a delivered power of 62.5 μW. These "wild" scenarios appeared to indicate that, despite mediocre conversion efficiency when presented with a 50Ω bench source, the antenna-connected harvester appears to work serviceably with single-band excitation from two very different ambient RF sources.

[0104] Switching Networks

[0105] Models of each of the three switching networks shown in FIGS. **3**, **5**, and **6** were constructed. A 5-band harvester model was used as a source in a simulation testbench. The goal of modeling was to characterize the summation benefit of each method over a naive serial combination of DC harvester outputs as a function of the excitation state of the 5-band harvester.

[0106] A SPICE model for the HSMS-282 diode used in serial summation was used as follows:

[0107] D(IS=4.8E−8, CJO=0.649E−12, VJ=5.6, BV=26.7, IBV=10E−4, EG=0.69, N=1.067, RS=7.8, XT1=2, M=0.5)

[0108] A. Test Setup: Multiexcitation Testing

[0109] Two fixed-resistance loads were used in each test scenario, 10 kΩ and 100 kΩ, and represent typical μW-scale loads that may be experienced in an energy harvesting device. A load capacitance of 10 nF was used. Two excitation power levels were used in each test scenario, −10 dBm and −20 dBm. In the multiexcitation tests, each excited band for a particular test was subjected to this excitation power and the other frequency bands were left unexcited. Every possible permutation of excited bands was tested for each data set, For each data point in each set, a transient simulation was allowed to run until a stable output voltage was reached, and the power across the load was then computed.

[0110] Low forward voltage and low reverse saturation current both must be achieved for summation network diodes to have a positive benefit. In all tests the HSMS-282 Schottky barrier diodes were used for summation as they have very low advertised forward voltage while maintaining low reverse saturation current. The parameters of the diode models used in the diode summation network are given in the SPICE model above.

[0111] In the modeled switching network including, active switches, bands left unexcited were bypassed by switches. The switch model used a 50Ω 'on' resistance and a 10 MΩ 'off' resistance, conservatively chosen values for low power analog switches such as the ADC1802 operating at low voltages. Switch power consumption for the ADG802 is under 10 nW per device. To estimate the overhead of the control logic, a TI MSP430G2553 microcontroller power consumption in low power mode (LPM3, with a crystal oscillator active) was assumed. 1. The total power consumption of switches and control logic is just under 1 μW, and all results involving intelligent switching reflect this overhead.

[0112] The diode summation network of FIG. **5** generally provided a benefit excepting the ease in which all five bands were excited. The simple diode summation network of FIG. **3** also reliably provided a benefit, but in general was less beneficial over the complete test space than the full diode summation network.

[0113] The intelligent switching summation network including active switches, however, provided a strong benefit at higher input power but was less advantageous and even became an impediment as excitation power dropped. This decrease in efficacy with very low excitation power is a symptom of the power draw of the logic system for the intelligent switching network, and therefore is dependent on specific implementation.

[0114] From the foregoing it will be appreciated that although specific embodiments of the invention have been described herein for purposes of illustration, various modifications may be made without deviating from the spirit and scope of the invention.

What is claimed is:

1. A system comprising:

a wideband antenna configured to receive wireless signals from at least a first type of signal source configured to transmit in a first frequency band, and at least a second type of signal source configured to transmit in a second frequency band, different from the first frequency band;

a first circuitry branch including:

a first bandpass filter configured to pass at least a portion of the first frequency band;

a first matching network coupled to the first bandpass filter; and

a first rectifier coupled to the first matching network:

a second circuitry branch including:

a second bandpass filter configured to pass at least a portion of the second frequency band:

a second matching network coupled to the first bandpass filter; and

a second rectifier coupled to the first matching network, wherein outputs of the first and second rectifier are configured to couple in series to an output;

a first switch positioned to disconnect the first rectifier from the output when a voltage provided by the first rectifier is below a first threshold; and

as second switch positioned to disconnect the second rectifier from the output when a voltage provided b the second rectifier is below a second threshold.

2. The system of claim **1** wherein the first and second switches comprise diodes.

3. The system of claim **1** wherein the first and second switches comprise active switches.

4. The system of claim **3** wherein the active switches comprise normally-open switches.

5. The system of claim **1** wherein the first and second switches comprise diodes and wherein the system further includes a first active switch positioned to disconnect the first rectifier from the output responsive to a first control signal and a second active switch positioned to disconnect the second rectifier from the output responsive to a second control signal.

6. The system of claim **5** wherein the system is configured to have the first and second diodes provide control during startup of the system, and the first active switch and the second active switch provide control during normal operation of the system.

7. A system comprising:

a wideband antenna configured to receive wireless signals over a first frequency range;

a plurality of circuitry branches, each of the plurality of circuitry branches including:

a respective bandpass filter to pass a different respective frequency range, each different respective frequency range being narrower than the first frequency range; and

a respective rectifier coupled to the respective bandpass filter, the respective rectifier configured to rectify a signal received from the respective bandpass filter;

wherein an output of a plurality of respective rectifiers are configured to be coupled in series to an output; and

a switching network coupled to the output and configured to disconnect selected one or ones of the plurality of respective rectifiers from the output

8. The system of claim **7** further comprising a load circuit coupled to the output, the load circuit configured to receive power from the output.

9. The system of claim **8** wherein the load circuit comprises a backscattering transponder.

10. The system of claim **8** wherein the switching network comprises a diode network.

11. The system of claim **8** wherein the switching network comprises a network of active switches.

12. The system of claim **8** wherein the switching network comprises a diode network and a network of active switches, wherein the diode network is configured to disconnect selected one or ones of the plurality of respective rectifiers from the output during a startup mode, and wherein the network of active switches is configured to disconnect selected one or ones of the plurality of respective rectifiers from the output after the startup mode.

13. The system of claim **7** wherein component values in at least one of the plurality of circuitry branches are selected based, at least in part, on minimizing reflected energy at the wideband antenna at the respective frequency range and maximizing impedance of circuitry branches adjacent the at least one f the plurality of circuitry branches at the respective frequency range.

14. The system of claim **7** wherein an impedance looking into each respective bandpass filter is real and matched to the wideband antenna.

15. A method comprising;

receiving wireless signals at an antenna;

filtering the wireless signals into at least two frequency bands to provide at least two filtered signals;

rectifying each of the at least two filtered signals to provide respective rectified signals; and

combining selected ones of the respective rectified signals to provide an output voltage.

16. The method of claim **15** wherein said combining selected ones of the respective rectified signals comprises selecting the ones of the respective rectified signals having an amplitude greater than a threshold.

17. The method of claim **16** wherein said selecting comprises activating switches to disconnect other ones of the respective rectified signals from an output.

18. The method of claim **15**, wherein the wireless signals include cellular and TV signals, and wherein the at least two frequency bands comprise a first frequency band associated with cellular signals and a second frequency band associated with TV signals,

19. The method of claim **15**, wherein combining selected ones of the respective rectified signals comprises applying the respective rectified signals to a diode network.

20. The method of claim **15**, wherein combining selected ones of the respective rectified signals comprises applying the respective rectified signals to a network of active switches.

21. The method of claim **20**, further comprising selecting a state for each active switch in the network of active switches.

22. The method of claim **21**, wherein selecting the state for each active switch comprises, for each active switch in the network of active switches:

changing as state of the active switch from an initial state to a changed state;

monitoring the output voltage after the state of the active switch changed;

selecting the changed state if the output voltage increased after the state of the active switch changed;

selecting the initial state if the output voltage decreased after the state of the active switch changed.

23. The method of claim **15**, wherein combining selected ones of the respective rectified signals comprises applying the respective rectified signals to a diode network during a startup mode and applying the rectified signals to a network of active switches after the startup mode.

24. The method of claim **15**, further comprising applying the output voltage to a load circuit.

25. The method of claim **24**, wherein the load circuit comprises a backscattering transponder.

(57) **ABSTRACT**

Energy harvesting circuits and associated methods are provided that employ multiple antennas to optimize the amount of energy that is harvested while at the same time making efficient use of tag space. In some embodiments, matching networks are chosen in a manner that optimizes the DC energy that is created from the harvesting process. In other embodiments, phase shifts are introduced into the received signals to allow the signals to be more efficiently combined after they are rectified.

MULTIPLE ANTENNA ENERGY HARVESTING

CROSS-REFERENCE TO RELATED APPLICATION

[0001] This application claims the benefit of U.S. Provisional Application No. 60/756,309, entitled "Multiple Antenna Energy Harvesting," which was filed on Jan. 5, 2006, the disclosure of which is incorporated herein by reference.

FIELD OF THE INVENTION

[0002] The present invention relates to energy harvesting circuits for harvesting RF energy transmitted through the air and converting it to DC energy for powering electronic devices such as an RFID tag or transponder.

BACKGROUND OF THE INVENTION

[0003] The harvesting of RF energy transmitted through the air for use in powering electronic devices is extremely important in a number of fields, such as radio frequency identification (RFID) systems, security monitoring and remote sensing, among others. For example, RFID systems consist of a number of radio frequency tags or transponders (RFID tags) and one or more radio frequency readers or interrogators (RFID readers). The RFID tags typically include an integrated circuit (IC) chip, such as a complementary metal oxide semiconductor (CMOS) chip, and an antenna connected thereto for allowing the RFID tag to communicate with an RFID reader over an air interface by way of RF signals. In a typical RFID system, one or more RFID readers query the RFID tags for information stored on them, which can be, for example, identification numbers, user written data, or sensed data.

[0004] RFID tags can generally be categorized as either passive tags or active tags. Passive RFID tags do not have an internal power supply. Instead, the electrical current induced in the antenna of a passive RFID tag by the incoming RF signal from the RFID reader provides enough power for the IC chip or chips in the tag to power up and transmit a response. One passive tag technology, known as backscatter technology, generates signals by backscattering the carrier signal sent from the RFID reader. In another technology, described in U.S. Pat. Nos. 6,289,237 and 6,615,074, RF energy from the RFID reader is converted to a DC voltage by an antenna/matching circuit/charge pump combination. The DC voltage is then used to power a processor/transmitter/antenna combination that transmits information to the RFID reader at, for example, a different frequency. In either case, the area of the tag or silicon die is valuable, and therefore it is advantageous to make the most efficient use of the space thereon. In addition, it is known that multiple antennas can be used to generate a DC voltage from an RF signal. For example, U.S. Pat. No. 6,734,797 describes a tag that uses two dipole antennas where the greater of the energies produced from the two antennas is the one that is selected and used. This, however, is not the most efficient use of tag space since the energy for the "loser" antenna is not used. Thus, there is a need for an energy harvesting circuit that is able to employ multiple antennas to optimize the amount of energy that is harvested while at the same time making efficient use of tag space.

SUMMARY OF THE INVENTION

[0005] In one embodiment, an energy harvesting circuit, and associated method, is provided that includes a plurality of antennas, wherein each of the antennas is tuned to the same particular RF frequency range. Each of the antennas is structured to receive an RF signal having the same particular RF frequency and output a respective AC signal. The circuit also includes a plurality of matching networks, wherein each of the matching networks is operatively coupled to a respective one of the antennas and is structured to receive the AC signal output by the respective one of the antennas. The circuit further includes a plurality of voltage boosting and rectifying circuits, wherein each of the voltage boosting and rectifying circuits is operatively coupled to a respective one of the matching networks and is structured to receive the AC signal received by the respective one of the matching networks and output a DC voltage signal by converting the received AC signal into the DC voltage signal. In addition, the DC voltage signals output by the voltage boosting and rectifying circuits are summed together to create a combined DC voltage signal, and the impedance of each of the matching networks is chosen in a manner so as to maximize the voltage level of the DC voltage signal that is output by the associated voltage boosting and rectifying circuit.

[0006] In another embodiment, an energy harvesting circuit, and associated method, is provided that includes a plurality of antennas provided in an antenna plane, wherein each of the antennas is tuned the same particular RF frequency range. Each of the antennas is structured to receive an RF signal having the same particular RF frequency range and output a respective AC signal. The circuit also includes a plurality of matching networks, wherein each of the matching networks is operatively coupled to a respective one of the antennas and is structured to receive the AC signal output by the respective one of the antennas. The circuit further includes a plurality of voltage boosting and rectifying circuits, wherein each of the voltage boosting and rectifying circuits is operatively coupled to a respective one of the matching networks and is structured to receive the AC signal received by the respective one of the matching networks and output a DC voltage signal by converting the received AC signal into the DC voltage signal. In addition, the DC voltage signals output by the voltage boosting and rectifying circuits are summed together to create a combined DC voltage signal, and the impedance of each of the matching networks is chosen so as to cause a voltage level of the combined DC voltage signal to have a minimum deviation as a function of angle of rotation as the antenna plane is rotated about a first axis. Alternatively, the impedance of each of the matching networks may be chosen so as to cause a voltage level of the combined DC voltage signal to have at least a predetermined minimum value as the antenna plane is rotated about a first axis. As still a further alternative, the impedance of each of the matching networks may be chosen by: (i) incrementally rotating the antenna plane through a plurality of angle increments about a first axis, (ii) trying a plurality of different inductance and capacitance value combinations for each LC tank circuit of each of the matching networks at each of the angle increments, (iii) measuring the combined DC voltage signal for each of the inductance and capacitance value combinations at each of the angle increments, (iv) determining which one of the inductance and capacitance value combinations produces a maximum voltage level for the measured combined DC voltage signals at any one of the angle increments; (v) choosing for each the LC tank circuit the one of the inductance and capacitance value combinations that produces the maximum voltage level.

[0007] In yet another embodiment, an energy harvesting circuit, and associated method, is provided that includes a plurality of antennas, wherein each of the antennas is tuned to the same particular RF frequency range, and wherein each of the antennas is structured to receive an RF signal having the particular RF frequency range and output a respective AC signal. The circuit further includes phase shifting and rectifying circuitry operatively coupled to the antennas. The phase shifting and rectifying circuitry is structured to: (i) receive each respective AC signal, (ii) create a plurality of out of phase AC signals by causing each respective AC signal to be out of phase with one another, and (iii) convert each of the out of phase AC signals into a respective DC voltage signal. The DC voltage signals are then summed together to create a combined DC voltage signal.

[0008] Therefore, it should now be apparent that the invention substantially achieves all the above aspects and advantages. Additional aspects and advantages of the invention will be set forth in the description that follows, and in part will be obvious from the description, or may be learned by practice of the invention. Moreover, the aspects and advantages of the invention may be realized and obtained by means of the instrumentalities and combinations particularly pointed out in the appended claims.

BRIEF DESCRIPTION OF THE DRAWINGS

[0009] The accompanying drawings illustrate presently preferred embodiments of the invention, and together with the general description given above and the detailed description given below, serve to explain the principles of the invention. As shown throughout the drawings, like reference numerals designate like or corresponding parts.

[0010] FIG. **1** is a block diagram of one embodiment of an energy harvesting circuit according to the present invention;

[0011] FIG. **2** is a schematic illustration of an embodiment of a square spiral antenna that may be used in the energy harvesting circuits described herein;

[0012] FIG. **3** is a schematic illustration of an embodiment of an antenna layout that may be used in the energy harvesting circuits described herein;

[0013] FIG. **4** is a Smith chart that may be employed to choose the matching networks as described herein;

[0014] FIG. **5** is a schematic illustration of an energy harvesting circuit as described herein positioned within the range of a suitable RF source;

[0015] FIG. **6** is a block diagram of an energy harvesting circuit according to alternative embodiment of the invention in which a phase shift is introduced into each of the received RF signals; and

[0016] FIGS. **7**, **8** and **9** are schematic illustrations of three particular embodiments of the energy harvesting circuit shown in FIG. **6**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0017] FIG. **1** is a block diagram of one embodiment of an energy harvesting circuit **5** according to the present invention. The energy harvesting circuit **5** may, for example, form part of an RF transponder, such as an RFID tag, for providing power thereto or form part of some other type of remote station for energizing a power storage device thereof or some other object of interest. The energy harvesting circuit **5** includes a plurality of antennas **10**A-**10**D, each of which is tuned to the same particular RF frequency range. As used herein, the term "RF frequency range" shall refer to a single RF frequency or a band of RF frequencies. As is known, each antenna **10**A-**10**D may have a tank circuit (not shown) that includes an inductor and a capacitor, wherein the inductance and capacitance values are chosen to tune the antenna **10**A-**10**D to the desired RF frequency range, i.e., the same particular RF frequency or band of RF frequencies. In this embodiment, each tank circuit is fixed (i.e., fixed inductor and capacitor) so that the antenna **10**A, **10**B, **10**C, **10**D is fixedly tuned to the RF frequency range of interest.

[0018] While four antennas **10**A-**10**D are shown in FIG. **1**, it should be understood that that is meant to be exemplary only, and that the plurality of antennas may include less than or more than four antennas (with each such antenna being operatively coupled to respective accompanying circuitry as described below). Furthermore, each antenna **10**A, **10**B, **10**C, **10**D may be, for example, a square spiral antenna **35** having the form shown in FIG. **2**, with the innermost end **40** being open and the outermost end **45** being connected to a matching network (matching network **15**A, **15**B, **15**C, **15**D shown in FIG. **1**) as described below. In this manner, the square spiral antenna **35** may be viewed as an asymmetric dipole, and thus the square spiral antenna **35** does not need a ground plane. Preferably, the length of the outermost segment **50** of the square spiral antenna **35** is about equal to a quarter of the wavelength of the particular RF frequency or center frequency of the band of RF frequencies to which it is tuned as described herein, and the total length of the square spiral antenna **35** (three segments) is about equal to one half of that wavelength.

[0019] FIG. **3** is a schematic illustration of one particular antenna layout that may be used in the energy harvesting circuit **5** shown in FIG. **1** that includes four antennas **35** positioned and spaced in the manner shown with the outermost end **45** of each antenna **35** being connected to the respective matching network **15**A, **15**B, **15**C, **15**D as described below. It has been observed that the conductor width and spacing of the antennas **35** in FIG. **3** can be varied without seriously degrading the performance measured as the DC output of the respective charge pumps **20**A, **20**B, **20**C, **20**D described below. Therefore, in the layout shown in FIG. **3**, it is possible to put four antennas **35** in an area that is slightly more than two times the area occupied by single antenna **35**.

[0020] Referring again to FIG. **1**, each antenna **10**A, **10**B, **10**C, **10**D is operatively coupled to a respective matching network **15**A, **15**B, **15**C, **15**D and charge pump **20**A, **20**B, **20**C, **20**D as shown in FIG. **1**. In particular, each antenna **10**A, **10**B, **10**C, **10**D is electrically connected to a respective matching network **15**A, **15**B, **15**C, **15**D, which in turn is electrically connected to a respective voltage boosting and rectifying circuit preferably in the form of a one or more stage charge pump **20**A, **20**B, **20**C, **20**D. Charge pumps are well known in the art. Basically, one stage of a charge pump essentially doubles the effective amplitude of an AC input voltage and stores the resulting increased DC voltage on an output capacitor. The voltage could also be stored using a rechargeable battery. Successive stages of a charge pump, if present, will essentially increase the voltage from the previous stage resulting in an increased output voltage. In operation, each antenna **10**A, **10**B, **10**C, **10**D receives energy, such as RF energy, that is transmitted in space by a far-field source, such as an RF source. The RF source may be, for example, an RF interrogator unit which transmits an RF interrogation signal, or a local radio station, in which case the RF energy comprises ambient RF energy in the vicinity of the energy harvesting circuit **5**. The RF energy received by each antenna **10**A, **10**B, **10**C, **10**D is provided, in the form of an AC signal, to the associated charge pump **20**A, **20**B, **20**C, **20**D through the associated matching network **15**A, **15**B, **15**C, **15**D. Each charge pump **20**A, **20**B, **20**C, **20**D rectifies the received AC signal to produce a respective DC signal **25**A, **25**B, **25**C, **25**D, wherein each DC signal **25**A, **25**B, **25**C, **25**D is amplified as compared to what it would have been had a simple rectifier been used. The individual DC signals **25**A, **25**B, **25**C, **25**D are then summed to produce a combined DC signal **30**, which may be used to power a circuit or charge a power storage device as described elsewhere herein. The individual DC signals **25**A, **25**B, **25**C, **25**D may be summed in any suitable manner, such as, without limitation, connecting them in parallel or connecting them in series to produce the combined DC signal **30**.

[**0021**] In one particular embodiment, each matching network **15**A, **15**B, **15**C, **15**D is chosen (i.e., its impedance is chosen) so as to maximize the output of the respective charge pump **20**A, **20**B, **20**C, **20**D in the form of the respective DC signal **25**A, **25**B, **25**C, **25**D (i.e., to maximize the DC signal **25**A, **25**B, **25**C, **25**D). In other words, each matching network **15**A, **15**B, **15**C, **15**D is matching the impedance of the respective antenna **10**A, **10**B, **10**C, **10**D to the respective charge pump **20**A, **20**B, **20**C, **20**D solely on the basis of maximizing the DC output of the respective charge pump **20**A, **20**B, **20**C, **20**D. In the preferred embodiment, each matching network **15**A, **15**B, **15**C, **15**D is an LC circuit of either an L topology (which includes one inductor and one capacitor) or a π topology (which includes one inductor and two capacitors) wherein the inductance of the LC circuit and the capacitance of the LC circuit are chosen so as to maximize the DC output of the respective charge pump **20**A, **20**B, **20**C, **20**D. In one embodiment, an LC tank circuit may be formed by the inherent distributed inductance and inherent distributed capacitance of the conducing elements of each antenna **10**A, **10**B, **10**C, **10**D, in which case the antenna is designed and laid out in a manner that results in the appropriate chosen L and C values.

[**0022**] In the preferred embodiment, each matching network **15**A, **15**B, **15**C, **15**D is chosen so as to maximize the output of the respective charge pump **20**A, **20**B, **20**C, **20**D using a trial and error ("annealing") empirical approach. In particular, various sets of inductor and capacitor values are used as matching elements in each matching network **15**A, **15**B, **15**C, **15**D, and the resulting output of the respective charge pump **20**A, **20**B, **20**C, **20**D is measured for each combination, and the combination that produces the maximum output is chosen. In this process, the input impedance of the charge pump (**20**A, **20**B, **20**C, **20**D) with each matching network (**15**A, **15**B, **15**C, **15**D) may be plotted as a point on a Smith chart with a color coding for the amount of energy harvested as shown in FIG. **4**. After a number of tries, it is easy to see a clustering of the color coded points to selectively choose other points in or around the cluster to achieve a near optimum value. FIG. **4** illustrates a number of points showing the results on a Smith chart. It is important to note that the matching achieved in this manner tends to optimize the asymmetric dipole configuration described elsewhere herein. The matching component values are indicated in FIG. **4** as circles on the Smith chart with grayscale indications of voltage at the charge pump (**20**A, **20**B, **20**C, **20**D) output as compared to the 0 to 5 volt grayscale on the right of FIG. **4**.

[**0023**] In this embodiment, the matching network (**15**A, **15**B, **15**C, **15**D) is chosen individually for each antenna (**10**A, **10**B, **10**C, **10**D) in the energy harvesting circuit **5** in the manner just described. Other embodiments are also possible and are described below.

[**0024**] As will be appreciated by those of skill in the art, each antenna **10**A, **10**B, **10**C, **10**D that is included in the energy harvesting circuit **5**, for example as laid out in FIG. **3**, will have a different polarization with respect to the transmitting antenna of the RF source that is determined by the relative angle of the antenna **10**A, **10**B, **10**C, **10**D in question to the polarization of the transmitting antenna of the RF source. Another embodiment of the invention, described below, chooses each matching network (**15**A, **15**B, **15**C, **15**D) in a manner whereby the relative polarization efficiency of each antenna **10**A, **10**B, **10**C, **10**D will be more efficiently utilized. In particular, in this embodiment, the energy harvesting circuit **5** is set up as shown in FIG. **1** with the antennas **10**A, **10**B, **10**C, **10**D being laid out as desired, for example in the manner shown in FIG. **3**. Then, as shown in FIG. **5**, the energy harvesting circuit **5** is positioned within the range of a suitable RF source **60**, preferably of a type identical or similar to the one with which the energy harvesting circuit **5** will ultimately be used, with the plane **70** in which the antennas are laid out **10**A, **10**B, **10**C, **10**D being substantially perpendicular to a line **65** that is taken through the center of the transmitting antenna of the RF source **60**. While the RF source **60** is transmitting, the antenna is incrementally rotated about the line **65**, preferably through 360 degrees (the rotation will be into and out of the paper in FIG. **5**). At each increment (each angle of rotation θ), the matching elements (the inductance and capacitance values) in each matching network **15**A, **15**B, **15**C, **15**D are varied over a set of different values (preferably predetermined), and with each such variation, the voltage level of the combined DC signal **30** is measured and recorded. The same set of inductance and capacitance values is used at each angle θ. In addition, at each angle θ, the set of values may and preferably will include instances where the values are different for one or more of the matching networks, i.e., each matching network will not have the same values. Once the rotation is complete, the measured and recorded levels of the combined DC signal **30** (as a function of the angle θ) are analyzed and the set of inductance and capacitance values yielding the minimum deviation in the combined DC signal **30** as a function of the angle θ is chosen. The matching networks **15**A, **15**B, **15**C, **15**D are then structured accordingly (i.e., to have the chosen inductance and capacitance values) in the final energy harvesting circuit **5**. As will be appreciated, this will result in the combined DC signal **30** having the minimum deviation in all orientations of the energy harvesting circuit **5** in the plane in which the antennas are laid out. As a result, at least some minimum amount of DC voltage will be able to be harvested in all orientations of the energy harvesting circuit **5**. This may be important if, for example, the circuit or object (or some component thereof) to be powered requires some minimum voltage level to operate. The matching networks **15**A, **15**B, **15**C, **15**D can be chosen as described above to ensure that at least that minimum voltage level is produced in all orientations (i.e., all angles of rotation θ) of the energy harvesting circuit **5**. In addition, once the matching networks **15**A, **15**B, **15**C, **15**D (i.e., the inductance and capacitance values therefor) are chosen in this manner (which may be time consuming) for one energy harvesting circuit **5**, multiple energy harvesting circuits **5** that meet the same parameters can be mass produced without having to go through the same trial and error steps.

[0025] In another embodiment, once the rotation is complete, the measured and recorded levels of the combined DC signal **30** are analyzed and the set of inductance and capacitance values yielding a maximum level for the combined DC signal **30** at any one orientation is chosen. The matching networks are then structured accordingly (i.e., to have the chosen inductance and capacitance values) in the final energy harvesting circuit **5**.

[0026] In the energy harvesting circuit **5** shown in FIG. **1**, it will be appreciated that each of the AC signals provided to the matching networks **15**A, **15**B, **15**C, **15**D will be in phase with one another. As a result, the individual antenna, matching, charge pump, etc. circuits have an RF supply in which the individual RF sinusoidal signals are in phase. This is analogous to the single phase rectifier design which is well known in DC rectifier circuitry. The removal of the minimum values of DC output is strictly on the basis of the angular variation of the antenna circuitry through matching the angles of orientation, and not the angles of the individual sinusoidal sources. Thus, in the energy harvesting circuit **5** shown in FIG. **1** the signals are not combined in the most efficient manner, and a more efficient manner is described below in connection with FIG. **6**.

[0027] FIG. **6** is a block diagram of an energy harvesting circuit **75** according to alternative embodiment of the invention in which a phase shift is introduced into each of the received RF signals. In particular, the energy harvesting circuit **75** includes a plurality of antennas **80**A-**80**C (similar to the antennas **10**A-**10**D), each of which is fixedly tuned to the same particular RF range. While three antennas **80**A-**80**C are shown in FIG. **6**, it should be understood that that is meant to be exemplary only, and that the plurality of antennas may include less than or more than three antennas (with each such antenna being operatively coupled to respective accompanying circuitry as described below). Furthermore, each antenna **80**A, **80**B, **80**C may be, for example, a square spiral antenna **35** having the form shown in FIG. **2**. In the case of four antennas, the layout may be as shown in FIG. **3**.

[0028] As shown in FIG. **6**, each antenna **80**A, **80**B, **80**C is electrically connected to respective phase shifting circuitry **85**A, **85**B, **85**C, which in turn is electrically connected to a respective voltage boosting and rectifying circuit preferably in the form of a one or more stage charge pump **95**A, **95**B, **95**C. In operation, each antenna **80**A, **80**B, **80**C receives energy, such as RF energy, that is transmitted in space by a far-field source, such as an RF source. The RF source may be, for example, an RF interrogator unit which transmits an RF interrogation signal, or a local radio station, in which case the RF energy comprises ambient RF energy in the vicinity of the energy harvesting circuit **75**. The RF energy received by each antenna **80**A, **80**B, **80**C is provided, in the form of an AC signal, to the associated phase shifting circuitry **85**A, **85**B, **85**C. Each phase shifting circuitry **85**A, **85**B, **85**C shifts the phase of the received AC signal in a manner such that the AC signals **90**A, **90**B, **90**C output by the phase shifting circuitry **85**A, **85**B, **85**C are all out of phase with one another. Thus, each phase shifting circuitry **85**A, **85**B, **85**C introduces a different degree of phase shift (which may actually be zero, in which case that particular phase shifting circuitry may be omitted, or, alternatively, be arranged to simply not shift phase or shift phase by 360 degrees). In one embodiment, the phase shift introduced by each phase shifting circuitry **85**A, **85**B, **85**C results in each AC signal **90**A, **90**B, **90**C being out of phase from the immediately adjacent signal AC signal **90**A, **90**B, **90**C by an equal amount. For example, for three AC signals **90**A, **90**B, **90**C, there would be 120 degrees separating immediately adjacent signals (e.g., one with 0 degrees phase shift, one with 120 degrees phase shift and one with 240 degrees phase shift, or, alternatively, one with 20 degrees phase shift, one with 140 degrees phase shift and one with 260 degrees phase shift).

[0029] The AC signal AC signal **90**A, **90**B, **90**C output by each phase shifting circuitry **85**A, **85**B, **85**C is provided to the associated charge pump **95**A, **95**B, **95**C. In an alternative embodiment, the AC signal AC signal **90**A, **90**B, **90**C output by each phase shifting circuitry **85**A, **85**B, **85**C may be provided to the associated charge pump **95**A, **95**B, **95**C through an associated matching network chosen and configured in the manners described elsewhere herein in order to optimize DC output. In either embodiment, each charge pump **95**A, **95**B, **95**C amplifies and rectifies the received AC signal to produce a respective DC signal **100**A, **100**B, **100**C. The individual DC signals **100**A, **100**B, **100**C are then summed (as described elsewhere herein) to produce a combined DC signal **105**, which may be used to power a circuit or charge a power storage device as described elsewhere herein. Because the AC signal **90**A, **90**B, **90**C received by the charge pumps **95**A, **95**B, **95**C are all out of phase with one another, they are able to be converted to DC and summed to produce the combined DC signal **105** in a more efficient manner, thereby leading to an increase on the voltage of the combined DC signal **105** over what would have been the case had the phase shifts described herein not been introduced. This is the case because the phase shifts cause the peaks and valleys of the AC signals **90**A, **90**B, **90**C be offset form one another rather then lined up with one another. It will also be appreciated that the multiphase embodiment provides a second degree of freedom in design for rotational purposes.

[0030] FIG. **7** is schematic illustration of one particular embodiment of the energy harvesting circuit **75**, labeled as **75'**. The energy harvesting circuit **75'** includes antennas **80**A, **80**B, **80**C as described above, each of which is fixedly tuned to the same particular RF frequency range and outputs an AC signal. Each antenna **80**A, **80**B, **80**C is connected to phase shifting and rectifying circuitry **110** that performs the functionality of the phase shifting circuitry **85**A, **85**B, **85**C and the charge pumps **95**A, **95**B, **95**C to produce the respective DC signals **100**A, **100**B, **100**C As described elsewhere herein, the DC signals **100**A, **100**B, **100**C are then summed (as described elsewhere herein) to produce a combined DC signal **105**. The phase shifting and rectifying circuitry **110** includes a well known Cockroft-Walton multiplier and consists of inductors **112**, **114**, and **116**, capacitors **118**, **120**, **122**, **124**, **126**, and **128**, and diodes **130**, **132**, **134**, **1365**, **138**, **140**, **142**, **144** and **146** connected as shown in FIG. **7**. The phase shifting and rectifying circuitry **110** receives each AC signal from the antennas **80**A, **80**B, **80**C, shifts the phases thereof such that each AC signal is out of phase with one another, and boosts and rectifies the resulting signals to produce the DC signals **100**A, **100**B, **100**C. The values of the inductors **112**, **114**, and **116** and the capacitors **118**, **120**, and **122** determines the degree of phase shift applies to each respective AC signal received from the antennas **80**A, **80**B, **80**C. FIG. **8** shows a similar embodiment of an energy harvesting circuit **75**" where two antennas are used with similar phase shifting and rectifying circuitry **110**'. It will be appreciated that four or more antennas may be used in a similar manner. FIG. **9** shows yet another similar embodiment of an energy harvesting circuit **75**"' where two antennas are used with similar phase shifting and rectifying circuitry **110**".

[0031] While preferred embodiments of the invention have been described and illustrated above, it should be understood that these are exemplary of the invention and are not to be considered as limiting. Additions, deletions, substitutions, and other modifications can be made without departing from the spirit or scope of the present invention. Accordingly, the invention is not to be considered as limited by the foregoing description but is only limited by the scope of the appended claims.

What is claimed is:

1. An energy harvesting circuit, comprising:

a plurality of antennas, each of said antennas being tuned to the same particular RF frequency range, each of said antennas being structured to receive an RF signal having said particular RF frequency range and output a respective AC signal;

a plurality of matching networks, each of said matching networks being operatively coupled to a respective one of said antennas and being structured to receive the AC signal output by said respective one of said antennas; and

a plurality of voltage boosting and rectifying circuits, each of said voltage boosting and rectifying circuits being operatively coupled to a respective one of said matching networks and being structured to receive the AC signal received by the respective one of said matching networks and output a DC voltage signal by converting the received AC signal into the DC voltage signal;

wherein the DC voltage signals output by the voltage boosting and rectifying circuits are summed together to create a combined DC voltage signal, and wherein an impedance of each of the matching networks is chosen in manner so as to maximize a voltage level of the DC voltage signal that is output by the associated one of the voltage boosting and rectifying circuits.

2. The energy harvesting circuit according to claim 1, wherein each of said voltage boosting and rectifying circuits is a charge pump.

3. The energy harvesting circuit according to claim 1, wherein each of said matching networks is an LC tank circuit.

4. The energy harvesting circuit according to claim 3, wherein an impedance of each of the matching networks is chosen in manner so as to maximize a voltage level of the DC voltage signal that is output by the associated one of the voltage boosting and rectifying circuits by, for each LC tank circuit of each of the matching networks: (i) trying a plurality of different inductance and capacitance value combinations for the LC tank circuit, (ii) measuring the voltage level of the DC voltage signal that is output by the associated one of the voltage boosting and rectifying circuits for each of the inductance and capacitance value combinations, and (iii) choosing one of the inductance and capacitance value combinations that produces a maximum voltage level of the DC voltage signal that is output by the associated one of the voltage boosting and rectifying circuits.

5. The energy harvesting circuit according to claim 1, wherein each of said antennas is a square spiral antenna having an outermost segment, a middle segment and an innermost segment, wherein a length of each outermost segment of is equal to about a quarter of the wavelength of the particular RF frequency or center frequency of the band of RF frequencies included in said particular RF frequency range, wherein a total length of each square spiral antenna is equal to about one half of said wavelength, and wherein the outermost segment of each of said antennas is operatively coupled to the associated one of said matching networks.

6. The energy harvesting circuit according to claim 5, wherein each square spiral antenna alone occupies a first spatial area, and wherein said antennas are provided in an antenna layout that occupies a second spatial area that is less than two times said first spatial area.

7. An energy harvesting method, comprising:

providing a plurality of antennas, each of said antennas being tuned to the same particular RF frequency range;

receiving a plurality of RF signals using said antennas, each of said RF signals having said particular RF frequency range;

outputting from said antennas a plurality of AC signals in response to receiving said RF signals;

converting each of the AC signals into a respective DC voltage signal after first passing each of the AC signals through a respective matching network having an impedance chosen in manner so as to maximize a voltage level of the respective DC voltage signal; and

summing each of the respective DC voltage signals together to create a combined DC voltage signal.

8. An energy harvesting circuit, comprising:

a plurality of antennas provided in an antenna plane, each of said antennas being tuned to the same particular RF frequency range, each of said antennas being structured to receive an RF signal having said particular RF frequency range and output a respective AC signal;

a plurality of matching networks, each of said matching networks being operatively coupled to a respective one of said antennas and being structured to receive the AC signal output by said respective one of said antennas; and

a plurality of voltage boosting and rectifying circuits, each of said voltage boosting and rectifying circuits being operatively coupled to a respective one of said matching networks and being structured to receive the AC signal received by the respective one of said matching networks and output a DC voltage signal by converting the received AC signal into the DC voltage signal;

wherein the DC voltage signals output by the voltage boosting and rectifying circuits are summed together to create a combined DC voltage signal, and wherein an impedance of each of the matching networks is chosen so as to cause a voltage level of the combined DC voltage signal to have a minimum deviation as a function of angle of rotation as said antenna plane is rotated about a first axis.

9. The energy harvesting circuit according to claim 8, wherein said first axis is a line taken through a center of a transmitting antenna of a source of said RF signal having said particular RF frequency range.

10. The energy harvesting circuit according to claim 8, wherein each of said voltage boosting and rectifying circuits is a charge pump.

11. The energy harvesting circuit according to claim 8, wherein each of said matching networks is an LC tank circuit.

12. The energy harvesting circuit according to claim 11, wherein an impedance of each of the matching networks is chosen so as to cause a voltage level of the combined DC voltage signal to have a minimum deviation as a function of angle of rotation as said antenna plane is rotated about a first axis by: (i) incrementally rotating said antenna plane through a plurality of angle increments, (ii) trying a plurality of different inductance and capacitance value combinations for each LC tank circuit of each of the matching networks at each of said angle increments, (iii) measuring the combined DC voltage signal for each of the inductance and capacitance value combinations at each of said angle increments, (iv) determining which one of the inductance and capacitance value combinations produces a minimum deviation in said measured combined DC voltage signals as a function of each of said angle increments; (v) choosing for each said LC tank circuit the one of the inductance and capacitance value combinations that produces the minimum deviation.

13. The energy harvesting circuit according to claim 8, wherein each of said antennas is a square spiral antenna having an outermost segment, a middle segment and an innermost segment, wherein a length of each outermost segment of is equal to about a quarter of the wavelength of the particular RF frequency or center frequency of the band of RF frequencies included in said particular RF frequency range, wherein a total length of each square spiral antenna is equal to about one half of said wavelength, and wherein the outermost segment of each of said antennas is operatively coupled to the associated one of said matching networks.

14. The energy harvesting circuit according to claim 13, wherein each square spiral antenna alone occupies a first spatial area, and wherein said antennas are provided in an antenna layout that occupies a second spatial area that is less than two times said first spatial area.

15. An energy harvesting method, comprising:

providing a plurality of antennas in an antenna plane, each of said antennas being tuned to the same particular RF frequency range;

receiving a plurality of RF signals using said antennas, each of said RF signals having said particular RF frequency range;

outputting from said antennas a plurality of AC signals in response to receiving said RF signals;

converting each of the AC signals into a respective DC voltage signal; and

summing each of the respective DC voltage signals together to create a combined DC voltage signal;

wherein said converting step is performed after first passing each of the AC signals through a respective matching network having an impedance chosen so as to cause a voltage level of the combined DC voltage signal to have a minimum deviation as a function of angle of rotation as said antenna plane is rotated about a first axis.

16. The energy harvesting method according to claim 15, wherein said first axis is a line taken through a center of a transmitting antenna of a source of each said RF signal having said particular RF frequency range.

17. An energy harvesting circuit, comprising:

a plurality of antennas provided in an antenna plane, each of said antennas being tuned to the same particular RF frequency range, each of said antennas being structured to receive an RF signal having said particular RF frequency range and output a respective AC signal;

a plurality of matching networks, each of said matching networks being operatively coupled to a respective one of said antennas and being structured to receive the AC signal output by said respective one of said antennas; and

a plurality of voltage boosting and rectifying circuits, each of said voltage boosting and rectifying circuits being operatively coupled to a respective one of said matching networks and being structured to receive the AC signal received by the respective one of said matching networks and output a DC voltage signal by converting the received AC signal into the DC voltage signal;

wherein the DC voltage signals output by the voltage boosting and rectifying circuits are summed together to create a combined DC voltage signal, and wherein an impedance of each of the matching networks is chosen so as to cause a voltage level of the combined DC voltage signal to have at least a predetermined minimum value as said antenna plane is rotated about a first axis.

18. The energy harvesting circuit according to claim 17, wherein said first axis is a line taken through a center of a transmitting antenna of a source of said RF signal having said particular RF frequency range.

19. The energy harvesting circuit according to claim 17, wherein each of said voltage boosting and rectifying circuits is a charge pump.

20. The energy harvesting circuit according to claim 17, wherein each of said matching networks is an LC tank circuit.

21. The energy harvesting circuit according to claim 20, wherein an impedance of each of the matching networks is chosen so as to cause a voltage level of the combined DC voltage signal to have at least a predetermined minimum value as said antenna plane is rotated about a first axis by: (i) incrementally rotating said antenna plane through a plurality of angle increments, (ii) trying a plurality of different inductance and capacitance value combinations for each LC tank circuit of each of the matching networks at each of said angle increments, (iii) measuring the combined DC voltage signal for each of the inductance and capacitance value combinations at each of said angle increments, (iv) determining which one of the inductance and capacitance value combinations produces at least said predetermined minimum value at each of said angle increments; (v) choosing for each said LC tank circuit the one of the inductance and capacitance value combinations that produces the at least said predetermined minimum value.

22. The energy harvesting circuit according to claim 17, wherein each of said antennas is a square spiral antenna having an outermost segment, a middle segment and an innermost segment, wherein a length of each outermost segment of is equal to about a quarter of the wavelength of the particular RF frequency or center frequency of the band of RF frequencies included in said particular RF frequency range, wherein a total length of each square spiral antenna is equal to about one half of said wavelength, and wherein the outermost segment of each of said antennas is operatively coupled to the associated one of said matching networks.

23. The energy harvesting circuit according to claim 22, wherein each square spiral antenna alone occupies a first spatial area, and wherein said antennas are provided in an antenna layout that occupies a second spatial area that is less than two times said first spatial area.

24. An energy harvesting method, comprising:

providing a plurality of antennas in an antenna plane, each of said antennas being tuned to the same particular RF frequency range;

receiving a plurality of RF signals using said antennas, each of said RF signals having said particular RF frequency range;

outputting from said antennas a plurality of AC signals in response to receiving said RF signals;

converting each of the AC signals into a respective DC voltage signal; and

summing each of the respective DC voltage signals together to create a combined DC voltage signal;

wherein said converting step is performed after first passing each of the AC signals through a respective matching network having an impedance chosen so as to cause a voltage level of the combined DC voltage signal to have at least a predetermined minimum value as said antenna plane is rotated about a first axis.

25. The energy harvesting method according to claim 24, wherein said first axis is a line taken through a center of a transmitting antenna of a source of each said RF signal having said particular RF frequency range.

26. An energy harvesting circuit, comprising:

a plurality of antennas provided in an antenna plane, each of said antennas being tuned to the same particular RF frequency range, each of said antennas being structured to receive an RF signal having said particular RF frequency range and output a respective AC signal;

a plurality of matching networks, each of said matching networks being operatively coupled to a respective one of said antennas and being structured to receive the AC signal output by said respective one of said antennas; and

a plurality of voltage boosting and rectifying circuits, each of said voltage boosting and rectifying circuits being operatively coupled to a respective one of said matching networks and being structured to receive the AC signal received by the respective one of said matching networks and output a DC voltage signal by converting the received AC signal into the DC voltage signal;

wherein the DC voltage signals output by the voltage boosting and rectifying circuits are summed together to create a combined DC voltage signal, and wherein an impedance of each of the matching networks is chosen by: (i) incrementally rotating said antenna plane through a plurality of angle increments about a first axis, (ii) trying a plurality of different inductance and capacitance value combinations for each LC tank circuit of each of the matching networks at each of said angle increments, (iii) measuring the combined DC voltage signal for each of the inductance and capacitance value combinations at each of said angle increments, (iv) determining which one of the inductance and capacitance value combinations produces a maximum voltage level for said measured combined DC voltage signals at any one of said angle increments; (v) choosing for each said LC tank circuit the one of the inductance and capacitance value combinations that produces the maximum voltage level.

27. An energy harvesting circuit, comprising:

a plurality of antennas, each of said antennas being tuned to the same particular RF frequency range, each of said antennas being structured to receive an RF signal having said particular RF frequency range and output a respective AC signal; and

phase shifting and rectifying circuitry operatively coupled to said antennas, said phase shifting and rectifying circuitry being structured to: (i) receive each said respective AC signal, (ii) create a plurality of out of phase AC signals by causing each said respective AC signal to be out of phase with one another, and (iii) convert each of said out of phase AC signals into a respective DC voltage signal;

wherein the DC voltage signals are summed together to create a combined DC voltage signal.

28. The energy harvesting circuit according to claim 27, wherein said phase shifting and rectifying circuitry comprises: (i) a plurality of phase shifting circuits, each of said phase shifting circuits being operatively coupled to a respective one of said antennas and creating a respective one of said out of phase AC signals, and (ii) a plurality of voltage boosting and rectifying circuits, each of said voltage boosting and rectifying circuits being operatively coupled to a respective one of said phase shifting circuits and converting a respective one of said of said out of phase AC signals into the respective DC voltage signal.

29. The energy harvesting circuit according to claim 28, wherein each of said voltage boosting and rectifying circuits is a charge pump.

30. The energy harvesting circuit according to claim 27, wherein a phase shift between each of said out of phase AC signals and each one of said out of phase AC signals that is adjacent in phase thereto is equal to 360 degrees divided by a total number of said antennas.

31. The energy harvesting circuit according to claim 27, wherein said phase shifting and rectifying circuitry includes a Cockroft-Walton multiplier.

32. An energy harvesting method, comprising:

providing a plurality of antennas, each of said antennas being tuned to the same particular RF frequency range;

receiving a plurality of RF signals using said antennas, each of said RF signals having said particular RF frequency range;

outputting from said antennas a plurality of AC signals in response to receiving said RF signals;

creating a plurality of out of phase AC signals by causing each of said AC signals to be out of phase with one another;

converting each of said out of phase AC signals into a respective DC voltage signal; and

summing each of the respective DC voltage signals together to create a combined DC voltage signal.

(57) **ABSTRACT**

A radio frequency energy harvester harvests RF energy from the environment. The energy harvester may include a local power source. The energy harvester may have an associated crystal radio antenna that harvests AM radio waves ubiquitously. The radio frequency energy harvested may be stored via a super capacitor. The stored energy may power a self-contained processing unit directly when the level of the energy harvested remains above a threshold level. However, if the energy harvested drops below the threshold level, the processing unit, which may include a radio, may switch to the local power source and/or a low power mode of operation. The low power mode of operation may reduce the amount of processing and/or transmitting by the radio. The processing unit may be part of a network of radios. The energy harvester may supply energy for a variety of applications, including building automation, industrial automation, power generation, and healthcare.

PASSIVE RF ENERGY HARVESTING SCHEME FOR WIRELESS SENSOR

PRIORITY AND CROSS-REFERENCE TO RELATED APPLICATION

This application claims priority under 35 U.S.C. §119(e) to provisional application Ser. No. 60/744,028, filed on Mar. 31, 2006, which is incorporated by reference in its entirety herein.

BACKGROUND

The present embodiments relate generally to harvesting environmental energy. More particularly, the present embodiments relate to harvesting energy from radio frequency (RF) signals to power a sensor node and/or wireless radio.

Wireless sensor networks (WSNs) of so-called "smart" sensors can be used in remote monitoring and control applications. However, in almost all applications that involve WSNs, there is a trade off between the need to sense and communicate useful information and the requirement to do so in an energy efficient manner. A WSN, once deployed, may be intended to work for long periods of time with only minimal human intervention. For instance, remote monitoring applications may include individual sensor nodes, numbering into the hundreds or even thousands, that each run on a limited supply of energy, such as a battery. As a result, with conventional sensor nodes, excessive on-board processing and, perhaps more importantly, frequent invocation of the sensor node's radio may rapidly deplete the on-board energy source. Therefore, there is a need to develop sensor network protocols and algorithms with energy-efficient and self-organizing capabilities.

Additionally, replacing depleted batteries may be inefficient or impractical. A network may include a large number of individual sensor nodes that may be difficult to access due to being implanted within a wall, a ceiling, a larger device, or a patient. Accordingly, there is also a need for novel energy harvesting schemes operable to power wireless sensor nodes, as well as automatically replenish on-board energy storage units.

BRIEF SUMMARY

By way of introduction, the embodiments described below include methods, processes, apparatuses, instructions, or systems for harvesting energy from freely available radio frequency (RF) signals. The energy harvested may power processing units, such as self-contained processing units or sensor nodes. A "passive RF energy harvesting system," or "harvesting system," may be connected to a processing unit having a processor and delivers power supply to the processing unit. Each harvesting system may be associated with a crystal radio receiver and/or an all pass or band pass filter operable to harvest energy from all radio frequency bands simultaneously or ubiquitously. As a result, more of the available RF energy may be harvested from the existing electromagnetic signals. The harvesting is ubiquitous since no tuning is required if the harvester is moved from place to place. Most of the RF energy scavenged may be harvested from amplitude modulated (AM) radio signals. The harvesting system may have a super capacitor that temporarily stores the RF energy captured. If the level of RF energy being harvested falls below a threshold level, an interrupt signal may be generated that directs the processing unit to conserve energy. For instance, the processing unit may limit on-board processing or reduce the number and/or strength of signals transmitted via a wireless radio, or both.

In a first aspect, a method harvests passive radio frequency energy. The method includes harvesting radio frequency energy using a crystal receiver. The method also includes powering a processing unit directly from the radio frequency energy being harvested when the radio frequency energy being harvested or an associated signal is approximately equal to or above a threshold level, and alternatively powering the processing unit from an on-board power source when the radio frequency energy being harvested or the associated signal is below the threshold level.

In a second aspect, a method harvests passive radio frequency energy. The method includes harvesting radio frequency energy via a crystal receiver and storing the radio frequency energy harvested on a super capacitor for subsequent use.

In a third aspect, a system harvests passive radio frequency energy. The system includes a network of radios within a building operable to direct the operation of building equipment to control a building environment of a building and at least one radio within the network being a sensor node operable to harvest radio frequency energy via a crystal receiver, the radio frequency energy harvested being used to power the sensor node.

In a fourth aspect, a computer-readable medium having instructions executable on a computer stored thereon is described. The instructions include monitoring for an interrupt signal that is triggered when the radio frequency energy being harvested via a crystal receiver falls below certain threshold, the radio frequency energy being used to at least partially power a sensor node or charge the battery on the harvesting system. The instructions also include automatically reducing the amount of power being expended by the sensor node if the interrupt signal is detected.

The present invention is defined by the claims herein. Nothing in this section should be taken as a limitation on those claims. Further aspects and advantages of the invention are discussed below in conjunction with the preferred embodiments and may be later claimed independently or in combination.

BRIEF DESCRIPTION OF THE DRAWINGS

The components in the figures are not necessarily to scale, emphasis instead being placed upon illustrating the principles of the invention.

FIGS. **1** and **1***a* are system block diagrams of an exemplary passive RF energy harvesting systems;

FIGS. **2** and **2***a* are schematics of additional exemplary passive RF energy harvesting systems;

FIG. **3** is a schematic of an exemplary network of sensor nodes;

FIG. **4** is a block diagram of an exemplary sensor node;

FIG. **5** is a top plan view of an exemplary network of sensor nodes within a building;

FIG. **6** illustrates an exemplary method of harvesting radio frequency energy;

FIG. **7** illustrates an exemplary interrupt handling method; and

FIGS. **8** and **9** illustrate exemplary antennas.

DETAILED DESCRIPTION OF THE DRAWINGS AND PRESENTLY PREFERRED EMBODIMENTS

The present embodiments are directed toward methods, processes, apparatuses, instructions, or systems for harvest-

ing freely available radio frequency (RF) energy from the environment, such as signals generated from amplitude modulated (AM) and frequency modulated (FM) radio stations. The RF energy harvested is used to power a "sensor node." The sensor node may include a processor, a sensor, an actuator, a wireless radio, and/or other components. The sensor node may be part of a network of radios in direct or indirect communication with one another, such as a wireless sensor network (WSN).

The sensor node may have an associated crystal radio receiver. The crystal radio receiver may operate as an all pass filter to harvest energy from all radio frequency bands simultaneously or ubiquitously. As such, more of the available RF energy may be captured for the given electromagnetic signals being received by the sensor node at a specific time.

The energy harvesting system may have an associated super capacitor that temporarily stores the RF energy received or a related signal, such as a voltage, a current, or other electrical parameter or signal associated with the RF energy harvested. In one embodiment, if a voltage associated with the RF energy being harvested falls below a given threshold, an interrupt signal may be generated that directs the sensor node to switch to a "low-power" mode to conserve energy. In low-power mode, the sensor node may reduce the amount of processing that an on-board processor performs. Alternatively or additionally, in low-power mode, the operation of an on-board wireless radio or transmitter may be altered and/or limited. For example, the wake-up period of the sensor nodes may be increased for energy saving purposes. Other manners of reduced sensor node operation may be employed to conserve energy being expended by the sensor node.

I. Crystal Radio Receivers

Generally, the embodiments discussed herein provide energy harvesting or scavenging for sensor nodes and/or wireless sensor networks (WSNs). In particular, AM RF signals may be harvested via crystal radio receivers to provide the primary, or even sole, source of power for the sensor nodes. Other crystal receivers may be used.

Crystal radios were popular by the 1950's, but are now almost obsolete. One of the key features of crystal radios is that they do not require batteries. The earplugs and/or speakers of a crystal radio may be powered solely by amplitude modulated (AM) radio signals. The crystal radio may employ a piezo-electric crystal, dielectric disk, oscillating crystal, or another type of crystal. The crystal may oscillate or vibrate due to the radio frequency signals being received. Exemplary crystal radio receivers are disclosed by U.S. Pat. Nos. 2,554,270, 2,805,332, 3,327,222, and 3,996,522, which are all incorporated herein by reference in their entireties. Other crystal radio receivers may be used.

The crystal radio technology may be used in new applications due to the advancement of semi-conductors and reduced power requirements of sensor nodes. In other words, the available energy that may be harvested from radio frequency signals via a crystal radio receiver, may contain sufficient energy to power milliwatt level instruments and micro-devices. Additionally, the size of a crystal radio antenna may be configured to be relatively small, ranging from a few to tens of centimeters. An antenna of this size may be used with a number of today's wireless sensor node applications.

Harvesting small amounts of energy from radio signals has been studied before, although not in the context of powering nodes in a WSN by AM RF signals. Previous studies have concluded that RF energy is of little utility unless a receiver is very close to a transmitter, such as a cell phone station. An alternate approach would be to introduce an RF signal transmitter for the explicit purpose of transmitting RF energy to a receiver that then harvests the RF energy to perform certain tasks. In other embodiments, such an approach may not be practical in the context of WSNs.

The energy available from RF signals in the unlicensed band, for e.g., the 2.4 GHz spectrum, may be typically too limited to be of any practical use. Such RF power harvesting may be impractical due to (1) very limited power being available (for an antenna size of 100 cm^2, the received power may be less than 0.1 milliwatt), and (2) very limited range (not only may a transmitter be required, but the sensor also may have to be placed very close to the transmitter). On the other hand, the principles on which crystal radios operate may finally permit the successful harvesting of energy from freely available RF signals.

As AM radio signals may be strong enough to power an earplug or a speaker, the energy available from RF signals may be more than past estimates indicated. A typical sensor node may require about 20 milliamps in active mode and 5 microamps in sleep mode, and the operating voltage required may be about 3 volts. Thus, the required power for a typical sensor node is comparable to the power that may be harvested via RF signals. Additionally, low-duty low-energy sensors may not require a transmitter, further reducing the amount of energy needed to power the sensor node. Therefore, RF signals may be a viable "free" and persistent (available 24 hours a day) energy source for a considerable amount of a given radio broadcast receiving area.

II. Estimation of Received Radio Energy

Table 1 below illustrates an estimation of the available RF energy in Princeton, N.J. from AM and FM RF signals transmitted by area radio stations. Through this rough estimation analysis, the "free" RF energy in the Princeton area is shown to be within the 10 milliwatt level. The estimation is based upon the Friis propagation model,

$$P_r = \frac{p_t G_t G_r \lambda^2}{(4\pi)^2 d^2 L},$$

TABLE 1

Here, p_t, p_r are the power of the transmitter and the receiver, respectively; G_t, G_r are the antenna gains of the transmitter and the receiver, respectively; λ is the wavelength of the RF signal in meters; d is the distance between the transmitter and the receiver; and L is the system losses ($L>1$). The estimation is based upon various assumptions, such as (1) radio station information (frequency and distance), (2) the transmitting power of AM radio stations being 10 kilowatt and FM stations being 5 kilowatt, (3) the antenna gains, G, are 1 (for a properly designed antenna, $G>1$), and (4) the system losses, L, are 1.

The results of the estimation indicate that (1) the total power received was 31.120 milliwatts, (2) the AM power received was 31.108 milliwatts, or 99.96% of the total power, and (3) the FM power received was 0.0126 milliwatt, or 0.04% of the total power. The estimation is based on ideal environments. In practice, L is more than 1 and the received power is less than the ideal case. Observing the Friis propagation model reveals that the effect of wavelength on the received power is more than that of the transmission power. Accordingly, signals with longer wavelength, such as AM signals, are much more suitable for RF energy harvesting.

A typical sensor node may require about 41 milliwatts in active mode and 1.5 microwatts in sleep mode. This power requirement is of the same order of magnitude as the power that is available from RF signals. With reasonable conditions, such as the sensor nodes being located near one or more AM radio stations and/or using relatively efficient antennas, the sensor nodes may be powered solely by the AM signal(s) and be kept running uninhibited all of the time. Alternatively, the sensor nodes may be powered primarily by the AM signal(s), if backed up by an on-board energy source.

III. Estimation of Available Energy from Other RF Signal Sources

As noted above, AM signals may include much more energy available for harvesting than FM signals. Energy from other RF signal sources also may be very small when compared with AM signals. For example, the RF signals from cell phones quickly attenuate as a function of distance. As a result, a cell phone signal may be used as a source of energy to power a sensor node only if the distance from the cell phone to the sensor node is about one meter or less.

Energy also may be received from IEEE 802.11.x protocol-based devices and television sets. As IEEE 802.11.x devices operate in the 2.4 GHz band, the energy available for harvesting may be even less than what is available from cell phones. Similarly, due to their high frequency, television signals may contribute very little towards harvestable energy. Therefore, AM signals may provide the best freely available RF source of power for wireless sensor nodes.

IV. Hybrid Scheme

A number of harvesting schemes may be utilized to capture energy from RF signals. As an example, harvesting energy from AM signals may not only be useful for indoor sensor nodes, but could also prove fruitful for outdoor sensor deployments.

In one aspect, the RF harvesting schemes discussed herein may combine two concepts. A sensor node may include crystal radio technology that is operable in conjunction with an energy storage unit, such as a battery and/or a capacitor. Once the output of the crystal radio receiver is connected to act as a source of energy and/or a "charger" to the energy storage unit, the system may be ready for use.

The sensor node may include a RF energy harvesting device that includes a so-called "energy harvesting antenna" operable to capture RF energy. The antenna may harvest AM, as well as FM, or RF signals. The antenna may be a spider antenna, braided antenna, omni-directional antenna, double-braided polyester rope, loop antenna, air coil loop antenna, sparrow antenna, Yagi-Uda antenna, or other type of antenna.

For example, FIG. **8** is an exemplary spider antenna. As shown, the antenna may have a number of legs of differing size. FIG. **9** is another exemplary antenna. Other shapes may be used, such as circular or disk shapes.

The antenna may be a laminated antenna having a number of wires etched onto a semi-conductor or other micro-device. The antenna wires may have either a flat or rounded shape, or be disk shaped. The antenna may have a number of spokes or legs, such as the spider antenna disclosed by U.S. Pat. No. 4,229,742, or the antenna may be a grid antenna similar to the one disclosed by U.S. Pat. No. 7,038,630, both of which are incorporated herein by reference in their entireties. As the antenna characteristics may be determined based upon the bandwidth and gain properties desired for a specific application, alternative antennas may be used.

In one embodiment, for both convenience and cost reduction purposes, a 1950's type of coil or wire antenna connected to the crystal radio receiver may be replaced by modern flexible printed circuit board. Printed circuit board similar to that used in conventional radio frequency identification (RFID) devices may be used. An exemplary RFID antenna is disclosed by U.S. Pat. No. 6,825,754, which is incorporated herein by reference in its entirety. Other types of printed circuit board material and shapes may be used as the antenna.

Once the RF energy is scavenged, the sensor node may regulate the energy within the crystal radio circuit and convert

the RF signals received to a DC signal, such as via a rectifier, without any frequency filtering. As an example, the RF signals harvested may not be filtered via low, high, or band pass filters. After the RF energy harvested passes through the rectifier, the energy may be stored on a super capacitor. However, since the voltage on the two sides of the super capacitor may not satisfy the requirements of the sensor node, a DC/DC converter and/or another capacitor may be employed (such as shown in FIG. **2**, discussed below).

Clean DC power may be available on both sides of the second capacitor. In addition, the DC/DC converter may sample the voltage on the super capacitor, and issue an interrupt to the sensor node once the voltage, which is an indication of the energy being stored and/or harvested, is lower than a certain threshold. The sensor node may then switch to the on-board power source of the harvesting system, such as a battery, a capacitor, or other energy storage device. If the energy being harvested provides a voltage level greater than that of an on-board energy storage device, the energy being harvested may power the sensor node directly, as well as provide a trickle charge to the on-board energy storage device. On the other hand, if the energy being harvested provides a voltage level lower than of the on-board energy storage device, the on-board energy storage device may provide power to the sensor node via a trickle discharge. The harvested RF energy is used to charge the battery under this case.

Therefore, the wireless and self-contained sensor nodes may employ a "hybrid" RF energy harvesting scheme. Each wireless and self-contained sensor node may be equipped with (1) a RE-based energy harvester and (2) an on-board power source. As long as there is enough available power from the RF energy harvester, the sensor node may operate using the RF power. Intermittently, however, the power from the harvester may not be at the threshold required to operate the sensor node. As a result, an interrupt may be generated that switches the sensor node to the on-board power source. The hybrid scheme ensures that the sensor node may be continuously operational while simultaneously greatly lengthening the life-time of the on-board power source.

There are some distinctions between RF energy harvesting as discussed herein and conventional harvesting schemes. With respect to solar cell techniques, the proposed RF harvesting schemes are not affected by the weather or time of day (darkness). The proposed RF harvesting schemes may provide a continuous power supply as most radio stations broadcast around the clock.

Additionally, the proposed RF harvesting schemes may provide more power than solar cells, such as with indoor environments, and at less cost, as typical solar cells may be more expensive than an RF antenna or coil. The costs associated with the proposed schemes may be further reduced if the antenna is implemented using technology similar to that of a RFID tag.

As compared to biomechanics-based harvesting schemes, the proposed RF harvesting schemes may be more suitable for sensor node applications. Conventional biomechanics harvesting methods tend to provide energy on an inconsistent basis and inconveniently toggle sensors periodically to recharge the power source. On the other hand, the proposed RF harvesting schemes may provide a consistent milliwatt-level power source. Toggling may be used with RF harvesting.

With respect to vibration or thermoelectric methods, it may be more difficult to find a vibration or heat source than it is to locate an AM radio station, especially in populated regions of the United States. When a free source is not available, the vibration or thermoelectric based schemes may require an artificial source. In many environments, such as an office or building, installation of such artificial energy sources may not be feasible.

In sum, new RF energy harvesting schemes are described that provide energy to self-contained sensor nodes. The schemes provide an improved crystal radio receiver and harvest AM RF signals as a source of power. The RF harvesting schemes are suitable for indoor applications that involve wireless sensor networks, such as building automation applications.

The RF harvesting schemes may be especially useful in areas having AM stations within about 20 kilometers to satisfy typical sensor node power requirements. However, the effective distance of the harvesting schemes may be extended. The antennas employed may be configured to harvest more energy and provide enhanced gain. Sensor nodes may be configured to be more energy efficient. For example, the sensor nodes may be programmed to operate more efficiently, such as spending more time in various reduced power modes of operation. Additionally, the sensor nodes equipped with RF energy harvesters may be supplemented with other types of energy harvesters, such as solar, piezo-electric, MEMS (micro-electro-mechanical systems), biomechanical, thermoelectric, and other harvesters. The RF harvesting schemes, except for requiring relatively nearby AM radio stations, may have no other substantial apparent limitations, such as the weather, periodic toggling, or other limits.

V. Exemplary RF Energy Harvesting Systems

FIG. **1** illustrates an exemplary passive RF energy harvesting system **100**. The system **100** may include an energy harvesting antenna **102**, a crystal radio receiver **104**, a super capacitor **106**, a DC/DC converter **108**, a sensor node **110**, a local power source **112**, and/or a communication antenna **114**. The system may include additional, fewer, or alternate components.

The crystal radio receiver **104** or crystal set may employ an antenna **102**. The crystal radio receiver **104** may not require a battery or power source except the power received from radio waves via the antenna **102**. The crystal radio receiver **104** may include an antenna wire, a tuning coil of copper wire, a rectifier, and other components. The crystal radio receiver **104** may be a passive radio receiver, not requiring an actively powered amplifier associated with conventional radios. The crystal radio receiver **104** may preserve electrical power from RF signals received via the antenna **102** and convert the RF signals to electronic power. The crystal radio receiver **104** may include various types of antennas and various "low-tech" or traditional electrical circuitry components, such as capacitors, resistors, inductors, and diodes. As such the crystal radio receiver **104** may be simpler and less expensive to manufacture than current "smart" radios, such as cellular phones.

The antenna **102** may be a conventional crystal radio antenna and include copper or silver wire coils, or a ferrite coil. The antenna **102** may be a Yagi, log-periodic, fiberglass, cable, repeater, or other type of antenna, including those discussed elsewhere herein. The antenna **102** may be manufactured from printed circuit board, aluminum, copper, silver, other metals, or other materials. The antenna may omni-directionally collect all of the available AM radio signals currently being received. The shape, size, circumference, and composition of the antenna **102** may be altered for a specific application and/or to enhance the gain associated with the antenna **102**.

The antenna **102** and crystal radio receiver **104** may act independently or in conjunction to harvest RF energy ubiquitously. The crystal radio receiver **104** may require no tuning and resonant with all of the available frequencies. As a result,

energy may be collected simultaneously from a number of radio stations, which may increase the average level of RF energy being harvested. This may be in contrast with typical receivers that may employ RC resonant circuits, which eliminate some RF signals from being harvested. In one embodiment, the antenna may have a physical length of between 10 and 20 cm.

The low power mode may include a number of algorithms and/or software instructions stored in the sensor node that direct the sensor node or an associated processor to conserve or reduce the amount of energy that the sensor node is using. A processing unit on the sensor node may perform reduced or limited processing in low power mode. The radio may change the message routing being employed based upon the amount of RF energy being sensed or harvested. A transmitter may transmit less often in low power mode, or not at all until the level of the RF energy being harvested returns to above a threshold or self-sustaining level. The transmitter may alter the type of signal being transmitted in low power mode. For example, the sensor node may not relay all the received communication packets, and/or the transmitter on the sensor node may transmit at a reduced power level. The transmission at a reduced power level may be intended to only reach the next or closest available sensor node or radio within the network.

The low power mode may include buffering or storing data, instead of constant or even intermittent transmission of information to other sensor nodes. With typical sensor nodes, the operation of the radio and/or transmitting information may require a substantial amount of energy. Therefore, reducing radio transmissions in low power mode may enhance the effectiveness of the RF harvesting schemes discussed herein.

The super capacitor **106** may store the RF energy being harvested. The capacitance of an electrode associated with the super capacitor **106** may be several hundred times the capacitance of a conventional double-layer capacitor. The super capacitor **106** may have one or more electrodes manufactured from titanium, palladium, aluminum, silicon, or other metals. Alternatively, the electrodes may be doped or have titanium, palladium, aluminum, silicon, or other metal coatings. The super capacitor **106** may be similar to those disclosed by U.S. Pat. Nos. 5,585,999 and 5,151,848, which are incorporated herein by reference in their entireties. Alternate types of super or other capacitors may be used.

The DC-to-DC converter **108** may operate to produce an output voltage signal and/or an interrupt signal **116** based upon a signal received from the super capacitor **106** or an electrical parameter of the super capacitor **106** monitored, such as a voltage, current, or other signal. The DC-to-DC converter **108** may be similar to the DC-to-DC converter disclosed by U.S. Pat. No. 6,417,653, which is incorporated herein by reference in its entirety. Alternate DC-to-DC converters may be used.

In one embodiment, the DC-to-DC converter **108** samples the voltage **120** on the super capacitor **106**. The voltage sampled may be a reflection the current level of RF energy being harvested crystal radio receiver **104** and/or stored by the super capacitor **106**. If the voltage sampled falls below a threshold level, such as a level required by the sensor node **110** to operate normally (i.e., with no power operating restrictions), then the DC-to-DC converter may generate a low-power interrupt **116** signal. The sensor node **110** may switch to a low or reduced power operating mode upon the receipt of the low-power interrupt **116**.

The on-board energy storage unit may be a capacitor or battery **112**. The on-board energy storage unit **112** may be on a trickle charge when the voltage sampled **120** from the super capacitor **106** remains above the threshold level (such as the actual battery or capacitor voltage) with the carryover RF energy harvested directly powering the sensor node **110**. Alternatively, the RF energy harvested may be sent directly from the DC-to-DC converter **108** to the sensor node **110** when the level of RF energy being harvested remains at or above the threshold level.

On the other hand, if the low-power interrupt **116** is sent to the sensor node **110**, the sensor node **110** may select **118** or switch to the on-board storage unit **112** as a direct source of power. Alternatively, when the voltage from the DC-to-DC converter falls below the threshold level (such as the actual capacitor or battery voltage), the sensor node **110** may automatically start to be powered by the on-board power storage unit **112** as the storage unit voltage would be higher than the output voltage of the DC-to-DC converter, as can be envisioned by FIG. **1**. Other manners of powering of the sensor node from the super capacitor, either solely or in conjunction with the storage unit, may be used.

The sensor node **110** may be mounted on a device that includes the other components shown in FIG. **1** or be associated with the other components in another fashion. The sensor node **110** may include a communication antenna **114** that provides for wireless communication with other sensor nodes. The sensor node **110** may include the components shown in FIG. **4** and discussed below, in addition to the components illustrated by FIG. **1**. The sensor node may include additional, fewer, or alternate components.

FIG. **1***a* illustrates another exemplary passive RF energy harvesting system **100**. In one embodiment, the system may be targeted to facilitate the powering of sensor nodes in an ad-hoc wireless sensor network. As each sensor node may have communication functionality through an on-board RF module, a message communication subsystem may not be required to be a part of the RF energy harvesting system **100**. Also, the RF energy harvesting system **100** may be purely passive, and thus, no registration with the FCC is required.

As shown in FIG. **1***a*, the system **100** may be connected to the sensor node and its communication antenna. The system **100** may be a band pass and/or all pass filter to match all AM frequencies in order to provide ubiquitous energy harvesting capability and also to harness the maximum available harvestable energy.

As shown in FIG. **1***a*, a super capacitor is introduced as an energy buffer to the rechargeable batteries. Super capacitors have large number of recharge cycles, but limited energy capacity when compared to rechargeable batteries. In one embodiment, since there is bound to be some variation of RF signal strength from time to time and place to place, the harvested RF energy may not be consistent. Thus, as can be seen from FIGS. **1** and **1***a*, harvested energy can be used to power the sensor node or charge the on-hoard power source (such as batteries) on each sensor node. Thus, the demands on recharge cycles of the batteries are relaxed and the battery lifetime may be improved.

FIG. **1***a* also illustrates the interrupt signal. If the harvested RF energy is not enough and falls below a certain threshold, the DC/DC converter (for example, a MAX1674/MAX1675) may trigger the sensor node via an interrupt signal as shown. The processor on the sensor node, upon receiving this interrupt, may measure the voltages of the super capacitor, V**1** **122**, and that of the battery, V**2** **124**. Depending upon what these measured values are, the sensor node may make intelligent decisions. In one embodiment, the sensor node controls a power switch **126** that is operable to switch between the super capacitor and the batteries as a source of power. An exemplary

flow chart of an interrupt handling process that may be implemented by software on the sensor node is illustrated by FIG. **7**.

FIG. **2** illustrates the circuit exemplary passive RF energy harvesting system **200**. The system **200** may include a crystal radio receiver **202**, an energy harvesting antenna **204**, a DC/DC converter **206**, a voltage output **208**, and an interrupt output **210**. The system may include additional, fewer, or alternate components.

As shown in FIG. **2**, the crystal radio receiver **202** may include a capacitor bank and a rectifier that converts the RF energy being received into a DC signal. The DC signal harvested may be stored upon the super capacitor C**9**. The DC/DC converter **206** may sense the voltage on the super capacitor C**9** and provide an output voltage VCC **210** to the sensor node, as well as the sensor interrupt **210** when the output voltage approximately reaches or falls below a threshold level. The sensor nodes may use RF energy harvesting systems having additional, fewer, or alternate components.

FIG. **2***a* illustrates another embodiment of the circuit of the exemplary passive RF energy harvesting system **200**. With respect to FIG. **1***a*, FIG. **2***a* illustrates in more detail from where V**1** **212** and V**2** **218** may be sensed. V**1** **212** may be sensed from the super capacitor C**2**. V**2** **218** may be sensed from the battery. FIG. **2***a* also shows the power switch **214**. The system may include additional, fewer, or alternate components.

VI. Exemplary Network

FIG. **3** illustrates an exemplary network **300** of wireless radios or sensor nodes **312**. The network **300** may utilize a dynamic routing algorithm that permits data transmitted to travel the shortest distance or link **314** between sensor nodes **312** to a destination, which decreases the required transmission time for a given message, as well as the required power level of that transmission. The destination may be another sensor node **312** or a control radio **316**. Each wireless and self-contained sensor node **312** and control radio **316** may have a dedicated processor, a receiver, and a transmitter. The network **300** may include additional, fewer, or alternate components.

Each sensor node **312** may communicate its associated routing information to every nearby or adjacent sensor node **312** or control radio **316**. After a sensor node **312** receives a data transmission, a processor of the sensor node **312** may determine what to do with that data, including whether to retransmit the data to an adjacent or nearby sensor node **312** or control radio **316**. The base station **316** may function as a network controller that directs the overall operation of the network **300**.

The network **300** may provide continuous communication with otherwise unavailable sensor nodes **312**. For instance, some sensor nodes **312** may become obstructed by obstacles, such as equipment, containers, furniture, or other items, or may fail. However, the network **300** may reconfigure itself around blocked paths by redirecting transmissions from one sensor node to the next until communication with a lost sensor node is re-established. The network **300** also may provide enhanced communication reliability between sensor nodes **312** as a single sensor node **312** may be in direct communication with a number of other sensor nodes **312**, as shown in FIG. **3**.

The network **300** may implement IEEE 802.15.4 protocols. Other protocol standards may be used. The network **300** may operate as a mesh network, as described in more detail below. Alternate control or routing algorithms/instructions may be used.

VII. Control of Building Equipment

One application of the sensor nodes described herein relates to a network that controls building equipment. The network may include multiple sensor nodes, each having a wireless radio, as well as one or more control radios or base stations that direct the network. Each sensor node may be a so-called "smart" sensor node that includes a receiver, a transmitter, a processor, memory, one or more sensors, an actuator, and/or other components. Each sensor node may transmit messages to a control radio acting as network controller. Alternatively, the network controller may be a dedicated processor. The network may have one or more network controllers and/or control radios. The term network herein may include the entire network, a sub-set of a network, a number of sensor nodes, one or more network controllers, one or more control radios, or a combination of sensor nodes with one or more network controllers or control radios.

A network controller may assimilate and analyze a number of messages received from a plurality of sensor nodes. In response to each of the messages received, the network controller may determine that a change in the currently operating building equipment, or the operating modes thereof, is in order. Subsequently, the network controller may transmit a message to one or more sensor nodes that direct the operation of building equipment. Upon receiving the message, a sensor node may alter the operation of building equipment.

The sensors associated with the sensor nodes/wireless radios may monitor specific parameters pertaining to building environmental conditions or specific operating equipment. The actuators associated with the sensor nodes may control the operation of certain building equipment. A sensor node may transmit the value of a parameter sensed by a sensor to the network. In response to the values of the parameters received, the network or another sensor node may automatically alter the operation of building equipment, such as by sending messages that operate the actuators that control the building equipment.

For example, the sensors may be temperature sensors that sense the temperature in an area of a building. Each temperature sensor may be connected with a sensor node having a wireless radio, the sensor nodes being dispersed throughout a building. Each sensor node having a temperature sensor may transmit a message to the network regarding the temperature sensed in the building area in which the sensor node is located. In response to the temperature information received, the network may direct that cooling, heating, ventilation, HVAC, emergency, or other building equipment be operated to alter the building environment of the building area in which the sensor node is located.

The network may employ multiple sensor nodes in each building area to monitor temperature. Conventional wall mourned temperature sensors and/or thermostats may be single point sources of information. However, the average value of individual temperature parameters received from a plurality of temperature sensors dispersed in a given building area may better reflect the actual temperature in the building area. Accordingly, the building environmental equipment may be directed to maintain the temperature of a building area closer to the desired temperature based upon the more accurate temperature information received.

The sensors also may be motion sensors that sense motion in a building area. Each motion sensor may be connected with a sensor node having a wireless radio, the sensor nodes being dispersed throughout a building. Each sensor node having a motion sensor may transmit a message to the network regarding the motion sensed in a building area. In response to the motion information received, the network may direct the operation of building equipment.

The motion detected may alert the network that a building area has recently become occupied or unoccupied. In response, the network may ensure that lighting equipment provides adequate light in or near the building area in which motion was sensed. The network may direct that building environmental equipment, such as cooling, heating, ventilation, HVAC, or other equipment, be operated to alter the building environment of the building area. The motion information received also may be used by the network to determine that a security breach has occurred. Accordingly, the network may trigger an alarm, secure passageways, and operate other security equipment in response to the security breach.

A sensor node having a wireless radio may be connected with an identification device located on an individual. After the sensor node located on the identification device transmits a message to the network, the network may determine the identification and/or location of the associated individual. In response, the network may transmit instructions to building environmental equipment to automatically alter the environmental conditions of the specific building area in which the individual is currently located based upon stored or transmitted environmental preferences associated with that individual.

In a building having numerous pieces of operating equipment, it may be desirable to automatically monitor various parameters associated with various pieces of equipment. For instance, in a power plant, refinery, factory, or other plant, it may be advantageous to monitor temperatures, pressures, alarms, tank levels, bilge levels, hydraulic levels, atmospheric conditions, operating pumps or fans, and other parameters. The change in various temperatures, pressures, levels, or equipment operating temperatures may indicate problematic conditions.

The network may automatically identify problematic conditions associated with operating building equipment. The various parameters monitored each may be sensed by a sensor located on a sensor node. The sensor node having a wireless radio may transmit the value of the parameter to the network, either periodically or upon being queried by the network or sensing an out of specification value. The sensor node may determine whether a parameter is within specification, i.e., a predetermined satisfactory range.

If a parameter is not within specification, the network may take corrective action to restore the parameter and/or building conditions to specification. For example, the running speed of a problematic piece of equipment may be shifted, increased, or decreased. The problematic piece of equipment also may be secured and an alternate piece of equipment may be started or placed on line to replace it. Additional, fewer, or alternate courses of action may be taken to correct problematic or out of specification parameters. Sensor nodes may be connected with or part of the equipment being controlled for wireless control of the equipment.

VIII. Mesh Network

In one embodiment, the network may include a number of sensor nodes, each having a wireless radio, arranged as a mesh network that also may be used to locate movable assets and/or operate building environmental equipment. The mesh network provides the capability of routing data and instructions between and among the network of radios. The mesh network permits data to be efficiently transmitted from one radio in the network to the next until the data reaches a desired destination.

The mesh network may be implemented over a wireless network or partially wireless network. Each sensor node having a radio within the network may function as a repeater that transmits data received from adjacent sensor nodes having radios to other nearby sensor nodes that are within range. The coverage area of the mesh network may be increased by adding additional radios. As a result, a network may be established that may cover an area of desired size, such as a floor of a building or an entire building.

Each sensor node having a radio within the mesh network is typically only required to transmit data as far as the next sensor node having a radio within the network. Hence, if a sensor node having a wireless radio has a limited power supply, the reduction in the distance that each sensor node is required to transmit permits lower power level transmissions, which may extend the operating life of the on-board power supply.

A number of protocols may be used to implement the mesh network. The sensor nodes may implement a protocol that uses low data rates and low power consumption. As noted above, the mesh network may employ devices that use very small amounts of power to facilitate significantly increased battery or power supply life. In some situations, power supply life may be extended by minimizing the time that the radio device of the sensor node is "awake" or in normal power using mode, as well as reducing the power at which a signal is transmitted.

Alternatively, the sensor nodes having wireless radios may implement a protocol that uses moderate or high data rates and power consumption. For instance, the sensor nodes may implement IEEE 802.11 protocols. An IEEE 802.11 LAN may be based on a cellular architecture where the system is subdivided into cells, where each cell is controlled by a base station. Other protocols may be implemented.

Additionally, by reducing the distance between sensor nodes, each sensor node having a wireless radio may be able to transmit signals at a reduced power level, which may extend the life of a power supply while the signals transmitted remain strong enough to reach an adjacent sensor node having a radio. The sensor nodes within the network may be synchronized such that each sensor node talks or listens at a particular time. Alternatively, one or more control radios may be generally active, while the remaining radios remain predominantly passive. The control radios may be hardwired directly to a power supply such that they are not confined by a limited power supply.

The mesh network may utilize the Zigbee protocol or other IEEE 802.15.4 Low-Rate Wireless Personal Area Network (WPAN) standards for wireless personal area networking. Zigbee is a published specification set of high level communication protocols designed for use with small, low power digital radios based upon the IEEE 802.15.4 standard. Other IEEE 802.15 standards also may be implemented, including those using Bluetooth or other WPAN or WLAN protocols or any other protocol.

The mesh network of sensor nodes may employ a dynamic routing algorithm. As a result, the mesh network may be self configuring and self mending. Each sensor node within the network may be able to identify neighboring sensor nodes. After receiving a message, a receiving sensor node may determine that it is not the sensor node closest to the destination and/or that it should not relay the message to another sensor node based upon the currently known configuration of operating sensor nodes. The receiving sensor node may wait a predetermined period and listen for another sensor node with a radio to relay the message. If after a predetermined time, the sensor node determines that the message has not been relayed as expected, the receiving sensor node may transmit or relay the message to a nearby sensor node.

By transmitting messages to only reach nearby or adjacent sensor nodes in the network, the messages within the network

may be transmitted at lower power. The low power transmission requires less energy from the on-board power supply of each sensor node. Additionally, the low power transmissions by the sensor nodes prevent one message from occupying the entire network and permits messages to be simultaneously transmitted from different sensor nodes and travel throughout the network of sensor nodes in parallel.

IX. Exemplary Sensor Nodes

FIG. **4** illustrates an exemplary sensor node or wireless radio **410**. The sensor node **410** includes a processor **412**, a wireless radio frequency transmitter and/or receiver **414**, a sensor **416**, an actuator **418**, a memory **420**, a clock **422**, a speaker **424**, a microphone **426**, and an on-board power supply **428**. The sensor node **410** may include additional, different, or fewer components.

For example, the sensor node **410** may be free of the sensor **416**, actuator **418**, memory **420**, clock **422**, speaker **424**, the microphone **426**, and/or power supply **428**. The sensor node **410** may include the processor **412** and the wireless transmitter and/or receiver **414**. For instance, the sensor node **410** may comprise the processor **412**, the wireless radio frequency transmitter and/or receiver **414**, the sensor **416**, the actuator **418**, and the power supply **428**. Or the sensor node **410** may comprise the processor **412**, the wireless radio frequency transmitter and/or receiver **414**, the sensor **416**, and the power supply **428**. The sensor node **410** may include other combinations employing additional, different, or fewer components.

In one embodiment, the sensor node **410** may be operable to automatically control building equipment and locate movable items within a building. In another embodiment, the sensor node **410** may be portable, such as in the case of being mounted upon a movable item, or affixed at a specific location or to an immovable item. The sensor node **410** may be a controller, actuator, sensor, locator or other device in a security, fire, environment control, HVAC, lighting, or other building automation system. The sensor node **410** may determine its present location, sense conditions within a building, report conditions within a building, generate a signal representative of a building condition, and/or respond to an interrogator. The sensor node **410** also or alternatively may actuate building control components. As a controller, the sensor node **410** may be free of the sensor **416** and/or the actuator **418**. In another embodiment, the sensor node **410** is a wireless device free of wired connections to other devices making the sensor node **410** self-contained and/or portable.

The sensor **416** may be a single sensor or include multiple sensors. The sensor **416** may be a temperature, pressure, humidity, fire, smoke, occupancy, air quality, flow, velocity, vibration, rotation, enthalpy, power, voltage, current, light, gas, CO_2, CO, N_2, O_2, chemical, radiation, fluid level, tank level, motion, Global Positioning System (GPS), infrared, or other sensor or combination thereof. The sensor **416** also may be a limit or proximity switch. Alternate sensors may be used.

The sensor **416** may be a motion sensor that detects when a portable sensor node **410** is moving. If it is sensed that the sensor node **410** is moving, the processor **412** may wake the sensor node **410** up from a sleep mode that draws less energy from the power supply **428**. Upon waking up, the sensor node **410** may transmit via the wireless transmitter **414** to the network a message indicating that sensor node **410** is moving.

The sensor **416** may be motion sensor that detects when there is movement within a predetermined distance. For example, the sensor **416** may be wall mounted to detect when an individual has entered a specific building area. If the building area was previously unoccupied, the sensor node **410** on which the sensor **416** is mounted may transmit a message to the network that the building area is no longer unoccupied. As a result, the network may direct that the environmental conditions be altered accordingly, such as increase the temperature during cold weather, decrease the temperature during hot weather, turn on one or additional lights, or adjust the room to the individual's personal preferences.

The sensor **416** may be a GPS unit capable of receiving GPS signals and determining the location of the sensor node **410**. The GPS unit may be able to determine the latitudinal and longitudinal coordinates, as well as the elevation, of the sensor node **410**. The location of the sensor node **410** determined by the GPS unit may be subsequently transmitted to the network via the wireless transmitter **414**.

The actuator **418** may be a single actuator or include multiple actuators. The actuator **418** may be a valve, relay, solenoid, speaker, bell, switch, motor, motor starter, turbine generator, motor generator, diesel generator, pneumatic device, damper, or pump actuating device or combinations thereof. For example, the actuator **412** may be a valve for controlling flow of fluid, gas, or steam in a pipe, or a damper controlling or redirecting air within an air duct. As another example, the actuator **412** may be a relay or other electrical control for opening and closing doors, releasing locks, actuating lights, or starting, stopping, and shifting motors and pumps. As a further example, the actuator **412** may be a solenoid that opens or closes valves, dampers, or doors, such as for altering the flow of fluid or air within piping or ducting. Alternate actuating devices also may be used.

The sensor node **410** may function as a controller or base station. The controller may be positioned at either a known or an unknown location. As a controller, the sensor node **410** interacts with other sensor nodes **410** for control or reporting functions.

The processor **412** is capable of processing data and/or controlling operation of the sensor node **410**. The processor **412** may be a general processor, digital signal processor, application-specific integrated circuit (ASIC), field programmable gate array, analog circuit, digital circuit, network of processors, programmable logic controller, or other processing device. The processor **412** may have an internal memory.

The sensor node **410** also may have a memory unit **420** external to the processor **412**. The memory unit **420** may store data and instructions for the operation and control of the sensor node **410**, such as discussed herein. Additional or alternate types of data also may be stored in the memory unit **420**.

A program may reside on the internal memory or the memory unit **420** and include one or more sequences of executable code or coded instructions that are executed by the processor **412**. The instructions may include monitoring a signal associated with radio frequency energy being harvested via a crystal radio receiver, the radio frequency energy being used to at least partially power a sensor node. The instructions also may include automatically reducing the amount of power being expended by the sensor node if the magnitude of the signal monitored approximately reaches or falls below a threshold level. The instructions may include directions to accomplish other functionality described herein.

The program may be loaded into the internal memory or memory unit **420** from a storage device. The processor **412** may execute one or more sequences of instructions of the program to process data. Data may be input to the data processor **412** with a data input device and/or received from a network. The program and other data may be stored on or read from machine-readable medium, including secondary storage devices such as hard disks, floppy disks, CD-ROMS, and

DVDs, or other forms of machine readable medium, either currently known or later developed.

The processor **412** is capable of directing the transmission or reception of data by the wireless transmitter or receiver **414**, the speaker **424** or the microphone **426**. For example, the processor **412** may direct the acoustic speaker **424** to transmit an ultrasound signal. The processor **412** may also direct the microphone **426** to receive an ultrasound signal and determine a distance from another device as a function of the received signal. Alternatively or additionally, the processor **412** may direct the wireless transmitter or receiver **414** to transmit data for determining the distance. Additionally or alternatively, the wireless transmitter **414** transmits a determined distance or distances as well as data regarding the processes and operation of the sensor **416** and/or the actuator **418**.

The wireless transmitter and receiver **414** or the speaker **424** may be alternate wireless transmitters capable of transmitting a signal for distance determination. Similarly, the wireless receiver **414** and microphone **426** may be alternative wireless receivers capable of transmitting a signal for distance determination.

FIG. **5** illustrates a floor layout for a network of sensor nodes having wireless radios **510** operating with one or more control radios **522** within a building **524**. The sensor nodes **510** may be dispersed throughout the building **524**. One or more of the sensor nodes **510** may be located in each room or other building area. Alternate dispersed arrangements of the sensor nodes **510** may be provided. While one control radio **522** is shown, a plurality of control radios **522** may be provided in other embodiments. Additional, different or fewer sensor nodes **510** and control radios **522** may be provided. While shown as a single floor of a building **524**, the network of sensor nodes **510** and control radios **522** may be distributed over multiple floors, a portion of the floor, a single room, a house, a structure, or any other building **524** or portion thereof.

The various sensor nodes **510** may be of the same configuration or a different configuration than each other. For example, some of the sensor nodes **510** may correspond to sensor arrangements, while other sensor nodes **510** may correspond to actuator arrangements. The same or different communication device, such as a wireless radio frequency transmitter and/or receiver, may be provided for each of the sensor nodes **510**. Alternatively, different communications mechanisms and/or protocols are provided for different groups of the sensor nodes **510**. The sensor nodes **510** may operate in an integrated manner for implementing one or multiple types of building automation control. Alternatively, different networks may be provided for different types of building automation, such as security, HVAC, heating, ventilation, and fire systems.

The sensor nodes powered by RF energy as discussed herein may be useful for a wide variety of applications, in addition to the building control functionality described above. For instance, the applications may include environmental and human body monitoring to military surveillance, building automation, and industrial monitoring. Each sensor node may facilitate one or more control, homeland security, reconnaissance, or other tasks. In one embodiment, the sensor node may be implanted internally within a patient, and sense and transmit data pertaining to a biological characteristic of the patient. The sensor nodes may be used for other applications.

X. Exemplary Method

FIG. **6** illustrates an exemplary RF energy harvesting method. The method may include harvesting RF energy **602**, storing the RF energy harvested **604**, monitoring a signal associated with the RF energy harvested **606**, and selecting an operating mode based upon the level of the signal monitored **608**. The method may include additional, fewer, or alternate actions.

The method may include harvesting RF energy **602**. RF energy may be harvested via a crystal radio receiver as discussed herein. Most of the energy harvested may be scavenged from AM radio signals. The RF energy may be harvested ubiquitously. The RF energy may be used to primarily or solely power a self-contained sensor node.

The method may include storing the RF energy harvested **604**. The RF energy or an associated signal may be measured from a super capacitor or other energy storage means. In one aspect, the RF energy harvestor may be used in unison with another type of energy harvester, such as a solar, biomechanical, thermoelectric, or vibration driven device.

The method may include monitoring a signal associated with the RF energy **606**. A voltage on the super capacitor may be monitored. Other signals related to the RF energy harvested also may be monitored.

The method may include selecting an operating mode based upon the level of the signal monitored **608**. The operating mode selected may relate to power constraints imposed upon the sensor node. If the level of the signal being monitored, such as a voltage signal or other signal, falls below a threshold level, the sensor node may be directed to operate in a low power mode, as discussed herein, to conserve energy until the amount of RF energy being harvested returns to a self-sustaining level with respect to the operating power requirements of the sensor node.

XI. Exemplary Method

FIG. **7** illustrates an exemplary interrupt handling method **700**. The method **700** may be implemented by software on the sensor node. As shown, the method **700** may use a state variable K having 2 states. When K=1, the power switch in FIG. **2***a* may connect pin A to pin Out, which in turn is connected to the pin labeled VCC. The voltage of pin VCC, which is connected to the sensor node, is equal to the output voltage of the DC/DC converter. Thus, in this case, the sensor node is powered through the energy harvester via the super capacitor and DC/DC converter. On the other hand, when K=2, the power switch connects pin B to pin Out and in this case, the sensor node is powered by the battery.

Ts in FIG. **7** is the wake-up period (which is configurable through software depending upon the application). The sensor node wakes up repetitively with time period of Ts. Each time when the sensor node wakes up, it may sense the environment, process the data, and transmit the date to the sink, if necessary. Then the sensor node may enter sleep mode, which costs almost no energy.

Tm in FIG. **7** is the maximum wake-up period allowed by the system. If Ts>Tm, the wake-up period is longer than the upper limit required by the system. Thus, the sensor node cannot provide spontaneous samples to satisfy the quality of service (QoS) requirements of the network.

Tp in FIG. **7** denotes a continuous block of time during which harvested energy is enough to support the continuous operation of the sensor node to execute for a time Te, which is the minimum time required by a sensor node to complete sensing tasks as required by an application. In other words, each time the sensor node wakes up, it may have to execute for at least a period of Te. And the sensor node may have to make a decision as to whether it powers itself from the energy harvester or through the battery for this amount of time. The

following brief analysis is presented to describe the novel sensor node operation that may be facilitated through the energy harvesting circuit.

Let the capacity of the super capacitor be represented by C. Then, the instantaneous energy E stored in the super capacitor is given by:

$$E=\tfrac{1}{2}CV_1^2.$$

If power rating of the sensor node is P, then the following equation holds

$$E+D'T_p=PT_e,$$

where E' is the derivative of E with respect to time Thus,

$$\begin{aligned}T_p &= \frac{PT_e - E}{E'} \\ &= \frac{PT_e - \frac{1}{2}CV_1^2}{CV_1V_1'},\end{aligned}$$

where V_1' is the derivative of **V1** and V_1' can be estimated in practice by taking the difference of the **V1** values at consecutive time intervals.

The flow chart shown in FIG. **7** may be described as follows. After receiving the interrupt **702**, the sensor node sends a control signal to the power switch such that the sensor node is powered through the battery **704**, since the energy on the capacitor may be depleted soon. The voltages **V1** and **V2** are measured by the sensor node **706**. Tp is also computed based on **V1** **708**, as shown in the above equation.

V2 is checked to see if it is low **710**. If it is, then all of the energy is going to be depleted soon. Recall that when the interrupt occurred, **V1** is already low. Thus, in this case, neither the energy harvester nor the battery can power the sensor node. The sensor node must take emergency actions, such as backup data **712** and notify its neighbors **714**. Finally, the sensor node sets Ts to be equal to Tp **716**, as well as sets K to 1 **718**. The rationale being that since the energy in the battery is going to be depleted soon, the node should wait in sleep mode **732** until enough energy has been harvested by the RF energy harvester.

When **V2** is not low, the decision is based on **V1**. If **V1** is low such that Tm≤Tp **720**, which means that the energy harvester cannot satisfy the sensor node energy requirements, then the sensor node once again has no choice but to use power from the battery source. Since there is enough battery energy (recall that **V2** is not low), the sensor node can be powered by the battery **728** through the current wake-up period Ts **726**. The neighbors also may be notified **730**. However, note that the energy from the harvester can still be used to charge the battery through the DC/DC converter. Thus, the system still benefits from the energy harvester even though the node is not powered directly by the energy harvester.

If **V1** is high enough to support the minimal energy requirements of the sensor during its wake-up period, i.e., Tm>Tp, then the sensor node can increase its wake-up period. In this case, Ts is set to be Tp **722** and the sensor node is powered by the energy harvester through the DC/DC converter **724**.

To summarize, the embodiments discussed herein facilitate the following complex sensor node behaviors: (1) switching the operating mode on the sensor node, such as standby or sleep modes; (2) sending a notification message to a sink via other sensor nodes; (3) saving important data to the flash memory on the sensor node, in case it is lost; (4) changing a sampling rate and transmission rate, and reducing the rates according to the voltages **V1** and **V2**, (5) adjusting an energy weighting factor in the network routing metric (if the voltages of the sensor node are not high enough, the use of this node as a router to route other wireless message packets is minimized or avoided), and (6) switching the input power source from the RF energy harvester to a battery.

The methods and systems discussed herein may use one, two, or more antennas. If two antennas are used, one antenna may be dedicated to the sensor node or communications unit, and the other antenna may be dedicated to the RF energy harvesting system, such as shown in the Figures. As both the sensor node and the energy harvester each may have their own dedicated antenna, switching a single antenna between the sensor node and the energy harvester may be alleviated.

The operational mode of the harvesting system and/or the sensor node may be switched by the sensor node itself. Additionally or alternatively, the RF energy harvester discussed herein may trigger the sensor node and provide voltage measurements. For energy conservation purposes, the harvesting system discussed herein may not switch operation modes based on. RF signals.

Therefore, the RF energy harvesters described herein may be directly connected to sensor nodes, purely passive and not needing to pass FCC requirements, and/or based on a bandpass or all pass filter for ubiquitous and wide spectrum RF energy harvesting. The systems discussed herein may facilitate advanced sensor behaviors. The system modes (active, standby and sleep) may be triggered by an interrupt signal and controlled by the sensor node, as compared to altering the operating mode according to received RF signals. The designs of the energy harvesting antenna may be different from known antennas. A super capacitor and/or a DC/DC converter may be employed by the energy harvester. Based on efficiency, size, and costs, the DC/DC converter may be provide benefits as compared to transformers. A buffered energy storage system may be constructed by the super capacitor and one or more rechargeable batteries. The harvesting system may improve battery life time.

While the invention has been described above by reference to various embodiments, it should be understood that many changes and modifications can be made without departing from the scope of the invention. The description and illustrations are by way of example only. Many more embodiments and implementations are possible within the scope of this invention and will be apparent to those of ordinary skill in the art. The various embodiments are not limited to the described environments, and have a wide variety of applications including integrated building control systems, environmental control, security detection, communications, industrial control, power distribution, and hazard reporting.

It is intended in the appended claims to cover all such changes and modifications which fall within the true spirit and scope of the invention. Therefore, the invention is not limited to the specific details, representative embodiments, and illustrated examples in this description. Accordingly, the invention is not to be restricted except in light as necessitated by the accompanying claims and their equivalents.

We claim:

1. A method of passive radio frequency energy harvesting, the method comprising:

harvesting radio frequency energy using a crystal receiver;

powering a processing unit only from the radio frequency energy being harvested when the radio frequency energy being harvested, or an indication of the amount of radio frequency energy being harvested, is above a threshold level;

generating an interrupt signal to switch the processing unit to a low power mode when the radio frequency energy

being harvested, or the indication of the amount of radio frequency energy being harvested, falls below the threshold level; and

alternatively powering the processing unit only from an on-board power source when the radio frequency energy being harvested, or the indication of the amount of radio frequency energy being harvested, is below the threshold level.

2. The method of claim **1**, wherein the crystal receiver employs an antenna that is fabricated from printed circuit board.

3. The method of claim **1**, wherein the radio frequency energy harvested is increased by a super capacitor before being used to power the processing unit.

4. The method of claim **1**, wherein the on-board power source is a battery or a capacitor.

5. The method of claim **1**, wherein the crystal receiver employs a ferrite coil antenna.

6. The method of claim **1**, wherein the radio frequency energy is harvested ubiquitously.

7. A method of passive radio frequency energy harvesting, the method comprising:

harvesting radio frequency energy using a crystal receiver;

powering a processing unit only from the radio frequency energy being harvested when the radio frequency energy being harvested, or an indication of the amount of radio frequency energy being harvested, is above a threshold level, wherein the processor unit is a self-contained sensor node operable to direct the operation of building equipment to control an environment of a building;

generating an interrupt signal to switch the processing unit to a low power mode when the radio frequency energy being harvested, or the indication of the amount of radio frequency energy being harvested, falls below the threshold level; and

alternatively powering the processing unit only from an on-board power source when the radio frequency energy being harvested, or the indication of the amount of radio frequency energy being harvested, is below the threshold level.

8. The method of claim **7**, wherein the processor unit has power requirements of greater than 10 milliwatts.

(57) **ABSTRACT**

A rectifier comprising a chain of transistors for RF-DC conversion. In order to compensate for the thresholds of the transistors, each transistor can be connected to a junction earlier or later in the chain. By using both p-type and n-type transistors in the same chain, the different types of transistors can be compensated in different directions allowing more transistors to be compensated. Additional transistors connected to the gates of transistors of the main chain can allow the transistors of the main chain to be forward compensated at one part of the input cycle and backward compensated in another part to minimize both the voltage threshold of the rectifier and the leakage current. The line for compensation of the voltage threshold during forward conduction can comprise a solid line or a transistor, and if a transistor is used it may be diode-connected.

RF-DC POWER CONVERTER

CROSS-REFERENCE TO RELATED APPLICATIONS

[0001] This application claims the benefit under 35 USC 119(e) of U.S. provisional application Ser. No. 62/011,957 filed Jun. 13, 2014.

TECHNICAL FIELD

[0002] Rectification, particularly for RF energy harvesting.

BACKGROUND

[0003] The vision of realizing Internet of Things (IoT) pervasively connecting large number of sensors and devices requires development of novel solutions that scavenges ambient energy to supply the power required for the operation of the sensors. Relying on batteries as the source of energy for wireless sensors impose several limitations including the need for routine maintenance/charging of batteries, operation interruption and cost involved in replacing batteries specially those employed in harsh environments, and challenges of scaling of battery-powered wireless sensors to millions of nodes. RF energy from ambient sources can be used to power efficiently the sensor networks with or without batteries. In addition, they can also be used to partially/fully charge other portable electronic devices to extend their battery life.

[0004] There is accordingly a growing interest in harvesting ambient energy to partially/fully supply the energy required for the operation of portable electronic devices. Scavenging energy from the ambient electromagnetic wave referred as RF energy harvesting is one of the most popular method for powering low-power wireless sensors. As most of today's integrated circuits are fabricated in CMOS technology, it is highly desirable to integrate RF energy harvesting systems with the rest of the system on a single CMOS chip for reduced cost and small form factor. RF powered devices are widely used in wireless sensor networks operating at power levels of 10 to 100's of μW. RF energy harvesting can be used in applications where the traditional energy sources such as light, vibrations are not available.

[0005] In an RF energy harvesting system **20** as shown in FIG. **1**, an antenna **22** receives the incident RF signal, an impedance matching circuit **24** maximizes the power transfer from the antenna to the power converter **26**, and a RF-DC power conversion circuit **26** converts the incident RF power to DC output power. The output DC voltage is stored in an energy storage component **28** (battery or capacitor) or can directly power the wireless sensors. The major challenge of scavenging RF energy is the limited signal strength of the RF waves and the low efficiency of the harvesting circuit at low input power.

[0006] The radiated signals are received by the RF energy harvesting system **20** and converted into a DC output voltage which is used to power-up the system. The radiated signals have to adhere to the regulation standards set by the federal communication commission (FCC). The unlicensed industrial, scientific and medical (ISM) band with a center frequency of 915 MHz operating at 902-928 MHz with a maximum effective isotropic radiated power (EIRP) of 4 W can be used for RF energy harvesting. The major challenge of scavenging RF energy is the limited signal strength of the RF waves and the low efficiency of the harvesting circuit. The signal strength is limited due to the attenuation in the signal due to the free space loss. Also, the power at the transmitter level cannot be increased without violating the FCC guidelines. Hence modification has to be done at the receiver side. The power consumption for the commercial sensor network nodes vary based on the manufacturers and has been estimated by various authors to be around 10 to 100 μW depending on the sensing application and the radio protocol. A multivolt supply voltage is typically required for the operation of the sensor circuitry.

[0007] The power harvester unit **20** comprising a multistage rectifier **26** is a key component in RF energy harvesting systems. It converts the incoming weak RF signal into a DC voltage. The performance of the rectifier unit **26** can be evaluated based on its power conversion efficiency (PCE) which is the ratio of power delivered to the load to the input power, based on sensitivity i.e. the minimum input power required for production of a DC voltage at the output and finally based on output DC voltage levels. To increase rectifier's PCE, the energy losses such as those introduced by the non-zero ON resistances of the rectifying devices must be reduced. To increase sensitivity and output voltage levels, rectifying devices with lower threshold voltages are required. Hence, these performance parameters of the power harvester are strongly affected by the threshold voltage of the rectifying devices. The power level has to exceed the threshold voltage of the rectifying device to turn on the rectifier unit in the RF-DC power conversion circuit. The minimum power is referred as the power-up threshold of the system. In terms of voltage level, a minimum input voltage is required for the circuit operation and is referred as the dead-zone of the rectifier.

[0008] The performance of an RF energy harvesting system **20** is significantly affected by the threshold voltage of the rectifying device **26**, the voltage that is required to turn on the semiconductor devices used as rectifying devices. A rectifying device **26** with lower threshold voltage enables the operation of RF-DC power converter **26** at low input power levels significantly reducing the power-up threshold of the rectifiers, and increasing the output voltage level for the same input power. The threshold voltage of device can be reduced using different technology-based approaches for the devices including silicon-on-sapphire (SOS), schottky diodes such as silicon-titanium schottky diodes or SMS and the HSMS diodes, special low-threshold-voltage transistors in CMOS process, and floating gate transistors which store a precharged voltage at the gate to lower the threshold voltage. The drawback of using technology-based approaches is additional fabrication steps that increases the production cost and prevents integration of RF energy harvester in mainstream Complementary Metal-Oxide-Silicon Integrated Circuits (CMOS ICs). Active/passive circuit techniques can be alternatively used to reduce the threshold voltage of the device. Active technique requires an external power source or secondary battery and is generally used in active sensors or active RFID. This enables more sophisticated applications at the price of increased cost and maintenance. Passive techniques do not require an additional source of energy but may require additional circuit where an auxiliary rectification chain is used to generate the compensating threshold voltage for the main RF-DC power conversion circuit. The auxiliary chain requires additional power and occupies additional area. An internal threshold voltage cancellation circuit was introduced in Kocer et al. where the compensating voltage was generated passively and stored in a capacitor that is applied at the gate-source terminal of the MOS transistor. This technique requires a large resistance and high capacitance value which leads to a large area on the chip. A self-biasing technique consisting of an off-chip high impedance resistive network was used by Li et al. to provide DC biasing voltages. Another technique can be using floating gate transistors storing a pre-charged voltage at the gate lowering its threshold voltage. The threshold voltage can be varied by changing the body-source potential of the transistor. This technique requires an additional pre-charge phase making it unsuitable for fully battery-less applications. The RF-DC power conversion circuit consisting of NMOS transistors with grounded body terminal leads to an increase in the threshold with the number of stages due to the body effect. This degrades the efficiency of the power conversion circuit. The body terminal of the transistors can be dynamically controlled using additional circuit or floating well devices. The floating well technique generates undesirable substrate current. Also, a triple-well source-body connected device has high parasitic capacitance leading to reduced efficiency. A cross-coupled differential scheme was used in Sciorcioni et al. consisting of triple-well NMOS and standard PMOS transistors to reduce the threshold voltage. A self-compensation scheme based on the Dickson topology was introduced in Curty et al. consisting of triple-well NMOS transistors to provide individual body biasing. The compensating voltage was provided by connecting the gate terminal to later stages. The design of the power converter in the works was focused on only reducing the threshold voltage neglecting the key role played by the reverse leakage current in introducing power losses. The reduction in threshold voltage increases the reverse conduction current causing additional loss.

[0009] To address the trade-off between the reduced threshold voltage and increased leakage current, Lee et al. proposed use of high speed comparators to control the reverse leakage current. The use of comparator increases the power consumption and limits the usefulness of this technique to low-frequency applications. Dynamic CMOS Dickson pump has been designed in previous works to eliminate the V_{th} drop while reducing the reverse leakage current. These circuits are designed for digital application with no emphasis on low-power operation. Differential-drive (**4**T-cell) architecture with the cross coupled bridge configuration and its variant has been used in previous works to reduce the threshold voltage as well as lower the leakage current. Differential circuit requires a PCB balun for the single-ended to differential conversion or differential antenna. Also, the differential circuit requires triple-well NMOS transistors and larger number of rectifying devices for the same number of stages compared with single-ended one.

SUMMARY

[0010] A power conversion circuit is provided having a first input line and a second input line, the first and second input lines configured to receive an alternating voltage differential between the first and second input lines, a multi-stage rectifier comprising transistors arranged in series, each transistor having a gate, a source and a drain, adjacent transistors of the series being connected so that for adjacent p-type transistors the drain of the left p-type transistor is connected to the right adjacent source of the right p-type transistor and source of the right p-type transistor is connected to the left adjacent drain of the left p-type transistor, for adjacent n-type transistors the source of the left n-type transistor is connected to the right adjacent drain of the right n-type transistor and drain of the right n-type transistor is connected to the left adjacent source of the left n-type transistor, for a p-type transistor adjacent to an n-type transistor the source of the right p-type transistor is connected to the source of the left adjacent n-type transistor and drain of the left p-type transistor is connected to the drain of the right adjacent n-type transistor to form a junction, each junction being connected to one of the first input line and the second input line via a capacitor, with adjacent junctions having one junction of the adjacent junctions connected to the first input line and the other junction of the adjacent junctions connected to the second input line, the gate of each transistor of the multi-stage rectifier being connected to a respective junction that is not a junction formed by the connection of that transistor to an adjacent transistor but a junction in the previous stage for the p-type transistor or later stage for the n-type transistor, at least one of the transistor in the multi-stage rectifier being p-type and at least one being n-type.

[0011] In various embodiments, there may be included any one or more of the following features: There may also be an auxiliary chain of p-type transistors, each auxiliary transistor having a gate, a source and a drain, each transistor of the auxiliary chain being connected to a p-type transistor of the multi-stage rectifier in the main chain, so that the gate of the respective auxiliary transistor is connected to the source of the respective transistor in the main chain, the source of the respective auxiliary transistor is connected to the gate of the transistor in the main chain and also connected to the previous stage junction of the main chain which is N transistors away from the respective transistor, and the drain of the respective auxiliary transistor is connected to the drain of the respective transistor or to the junction of the later stage transistor in the main chain. There may also be a diode connected transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of previous stages which is N transistors away from the respective transistor. There may also be an auxiliary chain of n-type transistors, each auxiliary transistor having a gate, a source and a drain, each transistor of the auxiliary chain being connected to an n-type transistor of the multi-stage rectifier in the main chain, so that the gate of the respective auxiliary transistor is connected to the source of the respective transistor in the main chain, the source of the respective auxiliary transistor is connected to the gate of the transistor in the main chain and also connected to the later stage junction of the main chain which is N transistors away from the respective transistor, and the drain of the respective auxiliary transistor is connected to the drain of the respective transistor or to the junction of the previous stage transistor in the main chain. There may also be a diode connected transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of later stages which is N transistors away from the respective transistor.

[0012] There is also provided an auxiliary chain of transistors, each auxiliary transistor having a gate, a source and a drain, each transistor of the auxiliary chain being connected to a respective transistor of a main chain of a multi-stage rectifier in the main chain, so that the gate of the respective auxiliary transistor is connected to the source of the respective transistor in the main chain, the source of the respective auxiliary transistor is connected to the gate of the transistor in the main chain and also connected to the later stage junction of the main chain which is N transistors away from the respective transistor in the case that the respective transistor is n-type, or to the earlier stage junction of the main chain which is N transistors away from the respective transistor in the case that the respective transistor is p-type, and the drain of the respective auxiliary transistor is connected to the drain of the respective transistor or to the junction of a previous stage transistor in the main chain, in the case that the respective transistor is n-type, or to the junction of a later stage transistor in the main chain, in the case that the respective transistor is p-type.

[0013] In various embodiments, there may be included any one or more of the following features: the transistors of the main chain and auxiliary chain may be n-type and there may also be a p-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of later stages, such that the gate of the additional p-type auxiliary transistor is connected to the gate of the n-type auxiliary transistor and the source of the n-type and p-type auxiliary transistors are connected, and the drain of the p-type auxiliary transistors is connected to junction of the main chain which is at 'N' later stages from the respective transistor. The transistors of the main chain and auxiliary chain may be p-type and there may also be an n-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of earlier stages, such that the gate of the additional n-type auxiliary transistor is connected to the gate of the p-type auxiliary transistor and the source of the n-type and p-type auxiliary transistors are connected, and the drain of the n-type auxiliary transistors is connected to junction of the main chain which is at 'N' earlier stages from the respective transistor. There may also be a diode connected p-type or n-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of later stages which is N transistors away from the respective transistor. There may also be a diode connected p-type or n-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of earlier stages which is N transistors away from the respective transistor.

[0014] In any of the above embodiments, there may be included any one or more of the following features: There may also be an additional transistor connected in series with the multistage rectifier, the additional transistor having a gate, a source and a drain, the gate of the additional transistor being connected to the drain of the additional transistor. The gate of each transistor in the main chain may be connected to the junction of previous stages for p-type transistor and later stages for n-type transistor. N of the transistors in the multistage rectifier arranged in series may be n-type and all but N of the transistors in multistage rectifier arranged in series may be p-type. The second input line may be grounded. The body terminal of each p-type transistor may be connected to the respective drain and the body terminal of each n-type transistor may be either grounded or connected to the respective drain terminal.

[0015] These and other aspects of the device and method are set out in the claims, which are incorporated here by reference.

BRIEF DESCRIPTION OF THE FIGURES

[0016] Embodiments will now be described with reference to the figures, in which like reference characters denote like elements, by way of example, and in which:

DETAILED DESCRIPTION

[0047] There is provided a hybrid forward and backward threshold voltage compensation scheme for RF-to-DC power conversion. In an embodiment, PMOS transistors are used as rectifying devices in all stages except for the first few stages eliminating the need for triple-well NMOS transistors. The compensating voltage is provided by connecting the gate terminal of the PMOS transistors to previous stages, also referred to as back-compensation, and also by connecting the gate terminal of the initial few NMOS transistors to later stages. Using PMOS transistors as a rectifying device in all the stages except for the first few stages eliminate the need for triple-well NMOS transistors. Also, all the MOS transistors in the main rectification chain are compensated in the proposed scheme. In addition to the hybrid scheme, an adaptive method suitable for rectifying devices operating at low power level is proposed to control the ON/OFF operation of the MOS transistors in the main rectification chain. An auxiliary block consisting of PMOS transistor is introduced to control the switching of the MOS transistors in the main chain. The PMOS transistors in the main chain are back-compensated in the conduction phase and forward-compensated when not conducting; increasing the gate-source potential and reducing the reverse leakage. The controlling voltage of the transistors in the auxiliary chain is derived from the local node of the main chain. Moreover, a procedure for designing matching network to provide passive voltage amplification and maximum power transfer is proposed. The dead-zone of the power converter unit is obtained using Y parameter analysis and the matching circuit is designed at the point of maximum power transfer. The RF-to-DC power conversion circuit may be fabricated using conventional methods such as IBM's 0.13 μm CMOS technology.

[0048] Power Harvester Circuit

[0049] FIG. **1** shows a block diagram of the power harvester unit of an RF energy harvesting system **20**. In the RF energy harvesting system shown, the signal is received by an antenna **22**. An impedance matching circuit **24** comprising a high quality factor (Q) resonator is used to ensure that maximum power is transferred from the receiver to the rectifier block **26**. However, the matching network itself introduces some energy losses because of the limited quality factors of on-chip passive inductors and capacitors required to match the input impedance of the rectifier to the output impedance of the antenna. The high Q resonator can also provide passive voltage amplification of the input signal. Depending on the embodiment, the high Q resonator may have a fixed frequency or may be tuneable. The next block is the RF-to-DC power conversion circuit **26** that converts the RF signal to DC voltage. The rectifier preferably operates at low input power levels while providing high power conversion efficiency. Several rectifier units may be cascaded to increase the overall output voltage, referred collectively as a voltage multiplier. There may be a power management block (not shown) to control the flow of power from the energy harvester to the load. The harvested power is then finally used to charge an energy storage device **28** such as a battery or a capacitor, which in turn powers a load **30**. Alternatively, the energy storage device may be omitted and the load powered directly by the power harvester. The power management block may also be omitted with or without the energy storage.

[0050] Rectifier Circuit

[0051] In half-wave rectifiers, the rectifying device is conducting for half of the cycle, passing the input voltage to the output. However, the output voltage is lower than the input by the amount of voltage drop needed for turning ON the rectifying device. A half-wave rectifier can be implemented using diodes as shown in FIG. **2**A. The voltage drop across the device depends on the threshold voltage of the diode. FIGS. **2**B and **2**C show half-wave rectification circuits implemented using diode-connected NMOS and PMOS transistors respectively in CMOS technology. The voltage drop in this case depends on the threshold voltage of the transistor. Both diode-connected PMOS and NMOS transistors can be used as rectifying devices. FIG. **2**D shows the voltage doubler unit which is a cascade of two half-wave rectifiers. The voltage doubler rectifies the AC input in both the positive and negative cycles. Similar to the half wave rectification, the diodes are implemented by connecting the drain and the gate terminal of the MOS transistor together such that the transistor is always in saturation region in forward bias condition, as shown in FIGS. **2**E and **2**F.

[0052] The voltage doubler may be used as a basic unit in a power conversion circuit. FIG. **2**F shows an example voltage doubler. In the voltage doubler, each of the transistors conducts only during one half of the input cycle. M_{P1} conducts during the negative phase while M_{P2} conducts during the positive phase of the input cycle. Each of the transistors goes through the sub-threshold region, inverse region and the leakage region. The maximum voltage at the output of voltage doubler is $2\,Vamp-|VTP1|-|VTP2|$, where V_{amp} is the maximum amplitude of the input signal and V_{TP1}, V_{TP2} are the threshold voltages of the diode-connected transistors M_{P1} and M_{P2} respectively. Thus the maximum possible voltage is twice the RF signal's amplitude only when the threshold voltage of the transistors is equal to zero. To understand the operation of the voltage doubler in detail, we can look at the transient analysis of the doubler circuit of FIG. **2**F, as shown in FIG. **3**A. There are three regions of operation of the circuit as seen from FIG. **3**A. It is described as follows: the sub-threshold operation extends from $V_{in}=0$ to $V_{in}=|V_{TP}|$, where V_{in} is the input voltage. The current in this region is an exponential function of the input voltage. The inversion region extends from $V_{in}=|V_{TP}|$ to $V_{in}=V_{amp}$. The current in the in this region is a square function of the input voltage. In the inversion region, the output current reaches its peak value when $V_{in}=V_{amp}$. Finally, the leakage region extends from $V_{in}=0$ to the next $V_{in}=0$ in the negative half-cycle. The current that flows through transistor M_{P2} during this time interval is referred as reverse leakage current. Thus, the actual charge transfer mechanism is only for a short duration while other parameters such as subthreshold and reverse leakage currents have to be considered for the rest of the cycle.

[0053] Several voltage doublers can be cascaded to increase the overall output voltage. These voltage multipliers are also known as "charge pumps" and can generate a voltage several times larger than their input supply voltage. The Dickson multiplier with diode-connected transistors is commonly used for integrated applications. The Dickson multiplier of

FIG. **4**A is modified for low power energy harvesting applications by grounding the ϕ_2 (out of phase) clock terminal and applying the input signal at the ϕ_1 terminal. FIG. **4**B shows the conventional Dickson multiplier with the PMOS voltage doubler as a rectifier unit. The body terminal of the transistors is connected as shown in FIG. **4**B to further reduce the threshold voltage while the transistors are conducting. For example, in the positive phase of the input cycle, transistors M_2, M_{n-1} and M_{n+1} are conducting. The source of the transistors is at a higher potential compared to the body terminal. This reduces the threshold voltage in the conducting region. At the same time, transistors M_1, M_3 and M_n are in the reverse region (leakage operation). The gate-source and the body-source potential is zero for these transistors. Thus, the threshold voltage of transistors M_2, M_{n-1} and M_{n+1} while they are conducting is lower than the threshold voltage of the transistors M_1, M_3 and M_n which are in the reverse region in the positive input phase. Similarly, in the negative phase of the input cycle, transistors M_1, M_3 and M_n which are conducting have a lower threshold voltage than the transistors M_2, M_{n-1} and M_{n+1}.

[0054] To increase the output voltage of multi-stage rectifiers, the number of rectifier stages must be increased accordingly. However, as the number of stages increases the power conversion efficiency is reduced as larger number of the transistors dissipates more power. Also, the threshold voltage of the standard MOS transistor which lies around 450 mV in 130 nm technology, reduces the sensitivity of the power harvester block. As the number of stages in the rectifier increases, the power losses increases, reducing the overall efficiency. Too few of stages, leads to low output DC voltage even if the PCE is high. To achieve a high DC voltage, large transistors have to be used, leading to high leakage and parasitic losses whereas smaller transistor size affects the charge transfer leading to low DC voltage. The strategy while designing the multi-stage rectifier circuit of FIG. **4**B is as follows: The individual stages of the voltage doubler can be cascaded to increase the output voltage. As the number of stages increases, the output voltage increases. With the increase in the number of stages, the PCE decreases and the output voltage saturates. Hence the transistors as well as the pumping capacitors are scaled while increasing the stages. The scaling is done to maintain the incremental voltage per stage and the PCE relatively constant with the increase in the number of stages. Thus the PCE can be maintained with proper device scaling while increasing the DC voltage for a constant output power. The scaling of width and the pumping capacitance with the stages results in impedance looking into the rectifier to be unchanged so that the input power and thus the PCE remains constant. Thus, when designing a multistage rectifier unit one can optimize of number of stages and width of the transistors to maximize the PCE for a given output voltage.

[0055] The standard Dickson multiplier can be modified for designs involving energy harvesters where the input voltage is low. FIG. **4**A shows an N-stage conventional Dickson multiplier. A threshold self-compensation technique was described by Dickson. The gate of the transistor in this technique is connected to the adjacent source of the transistor instead of the traditional diode-connected structure. Thus, providing bias voltage equivalent to the incremental voltage across each stage. Based on this technique, a forward compensated topology was implemented by Papotto et al. where the bias voltage was increased by extending the gate length connection. FIG. **5** shows the basic forward compensated NMOS topology.

[0056] Threshold voltage reduction techniques requiring additional circuits are not suitable for integrated low power energy harvesting applications as these circuits occupy large areas and cause additional power dissipation. Passive threshold voltage reduction technique such as the self-compensation method of FIG. **5** does not require additional circuit and can reduce the threshold voltage. In the self-compensation method, the threshold voltage of the diode-connected NMOS transistors increases with the stages due to the body effect. The body effect can be dynamically controlled using additional circuits but generates undesirable substrate current. Another alternative is using triple-well process to individually bias the body terminal of NMOS transistors and reduce the threshold voltage variation. Additional parasitic capacitance is introduced due to the well structure increasing the losses at each node and affecting the overall efficiency.

[0057] Hybrid Forward and Back-threshold compensated power converter

[0058] In order to eliminate the need for triple-well processes, we propose a threshold voltage compensation technique scheme as described below. PMOS transistors are used instead of NMOS transistors as rectifying devices. As each PMOS transistor has its own n-well, the body of PMOS transistor can be biased individually without the necessity of a triple-well CMOS process. Unlike an NMOS transistor which needs a higher potential at the gate terminal to offset the threshold voltage, a PMOS transistor requires negative gate-source potential. Therefore, the threshold voltage of PMOS transistors can be reduced by connecting the gate potential to the previous node rather than later node. As shown in FIG. **6**A, alternating input voltage V_{in} is applied on first input line **100** to odd-numbered capacitors $C_1, C_3, \ldots C_n$. Ground voltage is applied on second input line **102** to even numbered capacitors $C_2, \ldots C_{n-1}$. Capacitor C_{n+1}, while also even-numbered, is shown as connected to ground by a separate line. A third line **104** accumulates voltage for the output and is connected to ground at one end and to output at the other. In this and other figures, the end of the line having more negative voltage, which in the embodiments shown is ground, is shown at the left of line **104** and the end of the line having more positive voltage, which in the embodiments shown is the output, is shown at the right of line **104**. The capacitors are each connected to line **104**, and are numbered in the order in which they are connected to line **104** from left to right. Each capacitor maintains a respective voltage differential between the respective input line it is connected to and the part of line **104** it is connected to. This voltage differential varies over time as current flows through line **104** between capacitors. Line **104** comprises transistors $M_1, M_2, M_3, \ldots M_{n-1}, M_n, M_{n+1}$ arranged in series, a transistor being arranged between each pair of adjacent capacitors and between capacitor C_1 and ground. Adjacent transistors define junctions **106**, the capacitors being connected to the junctions. The body terminal of each transistor is connected to the drain terminal of the same transistor, as shown by dotted lines. The gate of the first transistor (for n-level compensation, the first ‘n’ transistors) and the last transistor are connected to their respective drains. The gates of the other transistors are connected to the drain of the transistor n+1 transistors to the left of the respective transistor. The proposed scheme as shown in FIG. **6**A reduces the threshold voltages of all PMOS transistors except the first one leading to an increased output voltage. For an n-level compensation, for the proposed scheme, there will be ‘n’ initial PMOS transistors that will be uncompensated as seen from FIG. **6**A To solve this problem, ‘n’ uncompensated PMOS transistors are replaced by NMOS transistors with grounded body terminals as seen from FIG. **6**B. As shown in FIG. **6**B, the first transistor is an NMOS transistor with a source connected to the source of the PMOS transistor to its right to define a junction and has a gate connected to the junction n stages to the right of the junction defined by its source. That is, the gate is connected to the junction defined by the source of the PMOS transistor **2** (i.e, n+1) transistors to the right. The other transistors are PMOS and, apart from the last, each has a gate connected to a junction n stages to the left of the junction defined by its source. For the purposes of the preceding statement and statements about junctions elsewhere in this document, the grounded end of line **104** can be considered to be a junction **106**A one stage from the junction defined by the connection of M_1 and M_2. Thus the compensating voltage is provided by connecting the gate terminal to later stages for the first few NMOS transistors and connecting the gate terminal to previous stages for PMOS transistors. The scheme shown in FIG. **6**A and FIG. **6**B is level-1 compensation. The compensation level can be increased by connecting the gate terminal of PMOS to the source terminals of the transistor of the following stage rather than the source of its immediate neighbor. The last transistor of the multiplier is left uncompensated to reduce the leakage. FIG. **6**C shows the proposed level-3 hybrid forward- and back-compensated multiplier. As shown in FIG. **6**C, the first **3** (i.e., n) transistors are NMOS transistors with grounded body terminals. Each NMOS (more generally, n-type) transistor has its source on the left and drain on the right, and each PMOS (more generally, p-type) transistor has its drain on the left and source on the right, where “left” and “right” are defined so that that the end of line **104** with more positive voltage is the “right”, as shown in the figures. “Earlier” and “later” can also be used to mean “left” and “right”. While ground is shown in the figures to the left and the output to the right, the ground could also be to the right and the output to the left. See below for a discussion of the definitions of “source” and “drain”. The gates of these first **3** NMOS transistors are connected to the respective junctions **106** three (that is, ‘n’) stages to the right of the junctions defined by their respective sources. The remaining transistors except the last are PMOS transistors with gates connected to the junctions **106** three (that is, ‘n’) stages to the left of the junctions defined by their respective sources. Increasing the level of compensation leads to reduction in the threshold voltage which improves the forward conduction but also leads to increased reverse leakage current degrading the rectifier’s PCE. Only odd level compensation is used as it maximizes the source-gate potential of PMOS transistors due to the alternating voltage phase with successive nodes.

[0059] To find the optimum number of stages and level of compensation, extensive simulations were conducted. FIG. **7** shows the efficiency contour plots with different level of compensation and input power level. Maximum PCE at the lowest input power level is obtained when the level of compensation is one. As the level of compensation increases, the reverse current increases which causes additional power loss and degradation in efficiency. Hence level-1 compensation gives the maximum efficiency while level-3 or higher is advantageous in reducing the threshold voltage of the RF-DC power conversion circuit. FIG. **8**A shows the constant efficiency contour plot as a function of transistor width and the number of stages for level-1 compensation. Eight-stage of doubler design equivalent to 16-stage rectifier with transistor width of 13-μm and fifteen-stage of doubler design equivalent to 30-stage rectifier with transistor width of 28 μm gives the highest efficiency contour. The former one is preferred due to lesser area on the chip. The level-1 and level-3 compensated multi-stage rectifier are referred to as efficiency circuit and voltage circuit respectively Similarly for the voltage circuit constant efficiency contour plot as a function of width and the number of stages is plotted as shown in FIG. **8**B. Twelve-stage of doubler design equivalent to 24-stage rectifier with transistor width of 8 μm is selected based on the plot. For level-3 compensation, more body-grounded NMOS transistors are required compared with the level-1. Also, the reverse leakage loss is higher for level-3 compensation due to the larger compensating voltage compared with the level-1 compensation. Increasing the level of compensation lowers the minimum input voltage requirement whereas increasing the number of stages while lowering the width of the transistors was based on the design strategy discussed earlier.

[0060] During the positive input phase, transistors M_2, M_{n-1} and M_{n+1} in FIGS. **6**A-**6**C are conducting. Since the gate terminals are connected to the previous node V_{SG} in the positive phase (conduction) is relatively high compared to the conventional Dickson multiplier. However, in the negative phase when the transistors M_2, M_{n-1} and M_{n+1} should ideally be not conducting, the V_{SG} is higher compared to the conventional case. Thus the hybrid forward and back-threshold compensated scheme is effective in increasing the forward conduction current but increases the reverse leakage current at the same time. As seen in FIG. **7**, with the increase in the level of compensation the PCE degrades. The simulated maximum PCE of 28% degrades to 11% from level-1 compensation to level-3 compensation respectively. To ameliorate this issue an adaptive scheme is proposed to control the reverse leakage current.

[0061] Especially at extremely low input power (e.g. micro-watts power level), the reverse leakage current has a significant adverse effect on the PCE and the output DC voltage of an RF rectifier as proven by the following analysis. Considering a threshold-compensated transistor of a single-stage rectifier shown in FIG. **2**G driven by an input source $V_{in}=V_a \sin \omega t$ assuming the compensation voltage is modeled by V_C and its input and the output steady-state voltage waveforms shown in FIG. **3**B, the overall PCE is defined as

$$PCE = \frac{P_{out,forward} - P_{leakage}}{P_{input}} \tag{1}$$

[0062] where $P_{out,forward}$ is the output power delivered to the load when transistor is forward-biased, $P_{leakage}$ is the output power lost due to leakage when transistor is reverse-biased, and P_{input} is the input power. The forward region extends from $t=t_1$ to $t=\pi-t_1$ with the current $I_d(t)$ through the MOS transistor M_1 as seen in FIG. **3**B.

$$\frac{P_{out,forward}}{P_{input}} = \tag{2}$$

-continued

$$\frac{\frac{1}{\pi-2t_1}\int_{t_1}^{\pi-t_1} V_{out}\cdot I_d\cdot dt}{\frac{1}{\pi-2t_1}\int_{t_1}^{\pi-t_1} V_{in}\cdot I_d\cdot dt}=\frac{\frac{1}{\pi-2t_1}\int_{t_1}^{\pi-t_1}(V_a-V_{TH}+V_c)\cdot dt}{\frac{1}{\pi-2t_1}\int_{t_1}^{\pi-t_1} V_a\sin\omega t\cdot dt}$$

Assuming the ripple voltage variation A V is much smaller than the average output voltage V_o, the output voltage for the one-stage rectifier can be expressed as $V_o=V_a-V_{TH}+V_C$ where V_{TH} is the threshold voltage of the transistor. Performing integration on (2) gives the ratio of the output power in the forward region to the input power as

$$\frac{P_{out,forward}}{P_{input}}=\frac{\omega\cdot(\pi-2t_1)\cdot(V_a-V_{TH}+V_c)}{2V_a\cos\omega t_1} \tag{3}$$

[0063] The value of t_1 lies between $0<t_1<\pi/2$ based on the value of $V_{TH}-V_C$. The time t_1 indicates the onset of inversion region and is close to zero when the compensating voltage is near the threshold voltage and will be closer to $\pi/2$ when the compensating voltage is near-zero value. As seen in (3), the ratio of the output power in the forward region to the input power increases with increased voltage compensation in the forward region. In the reverse-biased region, the leakage current is expressed as

$$I_{leak}(t)=I_o\cdot(W/L)\cdot e^{(V_{gs}-V_{TH})\eta V_T}\cdot(1-e^{-V_{ds}/\eta V_T}) \tag{4}$$

[0064] Replacing the gate-source bias voltage by V_C, source-drain bias by $V_{in}(t)-V_{out}$ and V_{in} by V_a sin wt, the leakage current as a function of time can be expressed as

$$I_{leak}(t)=I_o\cdot(W/L)\cdot e^{(V_c-V_{TH})/\eta V_T}\cdot(1-e^{(V_a\sin\omega t-V_a+V_{TH}-V_c)/\eta V_T}) \tag{5}$$

[0065] where $(\pi-t_1)<t<(2\pi+t_1)$. With increase in the compensation, the power loss increases due to the higher leakage current. As seen in (3) and (5), the ratio of the output power in the forward region to the input power even though increases with larger threshold-voltage compensation, the losses in the leakage region is higher due to the increased compensation. This indicates the fundamental trade-off between the level of threshold-voltage compensation and the leakage current of the transistors.

[0066] In a field effect transistor, the "source" and "drain" terminals are defined by the direction of flow of charge carriers when the transistor is "on": charge carriers flow from the source to the drain. For an n-type transistor, the charge carriers are electrons and for a p-type transistor the charge carriers are holes. As electrons flow from negative to positive, the source of an n-type transistor is at a lower voltage than the drain and vice versa for a p-type transistor. FETs do not necessarily have any asymmetry between the source and drain terminals beyond this. In the present system, the relative voltages of the source and drain terminals reverse in the normal course of events, as the system is exposed to alternating current in order to rectify it. There are two possible approaches to defining which terminal is the "source" and which terminal is the "drain" in this circumstance. One possible approach is to say that which terminal is the "drain" and which terminal is the "source" varies over time depending on which terminal is at the higher voltage. Thus, by this first definition, the source of an n-type transistor is whichever of the source and drain terminals has the lower voltage at any given moment, and for a p-type transistor whichever has the higher voltage at a given momentA second approach, however, is possible where the desired conduction is in a particular direction only. In the present system, conduction in one direction is desirable and conduction in the other ("leakage") is undesirable, thus the source can be defined according to which terminal is the source when current flows through the transistor in the desired direction; which terminal is considered the "source" and which terminal is considered the "drain" does not change over time in this approach despite the change in voltages. In the discussion here concerning the source-gate voltage (V_{SG}), the first approach is used, i.e. the source-gate voltage is the voltage between the gate and whichever of the source or drain terminals that has the higher or lower voltage at a given time depending on if the transistor is p-type or n-type. In addition, while the sign of a source-gate voltage difference required to operate a transistor depends on whether the transistor is p-type or n-type, V_{SG} is discussed as if the voltage to operate the transistor is always positive for p-type transistor and negative for n-type transistor. For other purposes in this document including the claims, a version of the second approach to defining which terminal is the source and which is the drain is used in which the direction of desired current is based on the desired current direction through the device as a whole. Thus, throughout the figures, p-type transistors are shown as having their sources to the left and n-type transistors are shown as having their sources to the right.

[0067] A diode-connected transistor is a transistor in which one of the source and drain terminals is connected to the gate to cause the transistor to act as a diode. A diode connected FET allows charge carriers to flow from the terminal not connected to the gate to the terminal connected to the gate, if sufficient voltage is applied, and blocks charge carriers from flowing in the opposite direction. The diode connected transistor is diode connected because it is desired that current flow in one direction is allowed and in flow in the other direction blocked. Thus, following a version of the second approach above to defining which terminal is the source and which terminal is the drain based on desired current through the individual transistor, the source or drain terminal of a diode connected transistor that is connected to the gate would be by definition the drain of the diode connected transistor. However, in this document it is the desired current through the device as a whole that is used, thus in e.g. FIG. **9**A transistor M_{na} is diode-connected and the terminal connected to the gate is depicted as the source.

[0068] To investigate the effect of the level of threshold-compensation on the PCE of multi-stage hybrid threshold-compensated rectifiers, level-1 rectifier which is connecting the gate terminal to one previous node for the PMOS transistors (FIG. **6**A) and level-3 rectifier which is connecting the gate terminal to three previous nodes (FIG. **6**C) for the PMOS transistors are simulated to obtain constant maximum efficiency contour plots as shown in FIG. **7**. Increasing the level of compensation leads to reduction in the threshold voltage which improves the forward-conduction but also increases the reverse leakage current. In the multipliers as shown in FIGS. **6**A and **6**C, during the positive input phase, transistor M_n is forward-biased. Since the gate terminals are connected to the previous node, V_{sg} when forward-biased is higher compared to that of the conventional diode-connected case with no threshold-voltage compensation which increases the ratio of output power in the forward region to the input power. However, when the transistor M_n is reverse-biased, the V_{sg} is higher compared to the conventional diode-connected case increasing the reverse leakage current of the reverse-biased transistor. This can also be explained by the efficiency contour plots of the hybrid scheme as seen from FIG. **7**. The contour plots are simulated for constant efficiency with different level of compensation and input power levels. As seen from FIG. **7**, though with the increase in the level of compensation the threshold voltage reduces, the efficiency degrades at the same time which is due to the increased reverse leakage current. The simulated maximum PCE of 28% degrades to 11% from level-1 compensation to level-3 compensation respectively. Accordingly an adaptive scheme is proposed to control the threshold voltage and the reverse leakage current of the rectifying device dynamically to improve the PCE over a wide range of input power. Ideally, the threshold voltage of the rectifying device should be zero when the transistors are forward-biased while the threshold voltage should be high when the transistors are reverse-biased to prevent any leakage or the losses associated with it.

[0069] We propose an adaptive forward and backward threshold-voltage compensation scheme that use minimal additional circuitry to increase the threshold-voltage compensation when transistors are forward-biased and decrease the compensation voltage when they are reverse-biased. The PMOS transistors in the main rectification chain are back-compensated when forward-biased and forward-compensated when reverse-biased; increasing the forward-current and reducing the reverse leakage current dynamically.

[0070] Proposed Adaptive Threshold Voltage Compensation

[0071] The hybrid forward and back-compensated topology described above can be made adaptive using an auxiliary block controlling the gate-source voltage of the MOS transistors in the main rectification chain. The auxiliary structure may be realized using all PMOS transistors to allow for individual body biasing. Preferably the auxiliary blocks are designed using minimum number of PMOS transistors so that the power losses do not increase considerably due to the additional blocks. The controlling voltage of the transistors in the auxiliary chain is derived from the local node of the main rectification chain. Two possible implementation of the proposed adaptive threshold voltage compensation scheme are discussed in the following section, one using diode-connected PMOS transistors and the other solid-wired connection to adaptively adjust the level of the threshold-voltage compensation.

[0072] Using Diode-Connected Transistor for Back-Compensation

[0073] FIG. **9**A shows the hybrid forward and back-threshold compensated rectifier using diode-connected transistors for back-compensation. The back-compensation reduces the threshold voltage when the transistors are forward-biased and forward-compensation reduces the reverse leakage current when reverse-biased with the control signal derived from the local node. In the embodiment shown the last transistor M_{n+1} is left uncompensated to reduce the leakage. During the negative input phase, in which the transistor M_n is forward-biased, the transistor M_n is back-compensated by the diode-connected transistor M_{na} while the V_{SG} terminal voltage for the transistor M_{nb} lies below its threshold voltage resulting in transistor M_{nb} turned OFF. In comparison to the embodiment shown in FIG. **6**B, diode-connected transistor M_{na} lies on the line connecting to the gate of transistor M_n. Transistor M_{nb} lies on a different line not corresponding to a line in FIG. **6**B, providing a forward connection for the gate of transistor M_n when transistor M_{nb} is active. In the embodiment shown in FIG. **9**A p-type transistors are used, but n-type could also be used. Additional transistors of the opposite type may be used at one end as in FIG. **6**B. The back-compensation for the transistor M_n in the main chain enhances the forward current. During the positive input phase, in which the transistor M_n is reverse-biased, the V_{SG} terminal for transistor M_{nb} is enough to turn ON the forward connection thus reducing the V_{SG} bias of the transistor M_n to zero resulting in a reduced leakage current. FIG. **10**A shows the efficiency contour plot for the adaptive diode-connected scheme as a function of width and the number of stages of the rectifier. Generating contour plots are an effective way to optimize the number of stages and the width of the transistors to maximize the PCE while obtaining the required voltage. Twelve-stage of voltage doubler design equivalent to 24-stage rectifier with transistor width of 11 μm gives the highest efficiency contour. The width of the diode-connected transistor in the auxiliary chain should be comparable to the width of the transistors in the main rectification chain so that it provides low forward-resistance when the transistors are conducting. In an embodiment, the width of the diode connected transistor in the auxiliary chain may be 8 μm. The auxiliary transistor used for forward compensation to control the reverse-leakage is selected in an embodiment to be 480 nm, an order of magnitude smaller than the diode-connected transistor to minimize their power consumption and reduce the parasitic at the nodes of the main rectification chain. Larger transistor widths are avoided to reduce the parasitic at the nodes of the main rectification chain.

[0074] Also, for the diode-connected scheme, the auxiliary block is added for every alternate transistor starting from the later stages and adding the blocks towards the initial stages. The maximum PCE increases with the addition of the adaptive auxiliary blocks.

[0075] Using Solid Connection for Back-Compensation

[0076] FIG. **9**B shows the adaptive hybrid topology using solid wired connection instead of the diode-connected transistor for reducing the threshold voltage. When the transistors are in the conduction phase (forward biased) they are back-compensated with solid wired connection instead of the diode-connected transistors which prevents the forward-losses associated with it. In the embodiment of FIG. **9**B, as compared to FIG. **9**A, the transistors M_{na}, $M_{n-1})_a$ etc. are omitted and replaced by a solid wire connection as in FIG. **6**B, but the transistors M_{nb}, $M_{(n-1)b}$ etc. are retained. In the embodiment shown in FIG. **9**A p-type transistors are used, but n-type could also be used. Additional transistors of the opposite type may be used at one end as in FIG. **6**B. When the transistor M_n is reverse-biased (not in the conduction phase), the V_{sg} terminal voltage for the auxiliary transistor M_{nb} is large to turn ON the forward-connection and reduce the source-gate bias of transistor M_n. This decreases the reverse leakage current greatly. FIG. **10**B shows an efficiency contour plot for the solid-wired scheme as a function of width and the number of stages of the rectifier. Twelve stages of doubler design equivalent to 24-stage rectifier with transistor width of 10 μm gives the maximum efficiency contour. The efficiency contour plot for the solid-connection follows similar trend as the diode-connected one. With the increase in the width of the transistors while maintaining the number of stages, the efficiency initially increases and then degrades due to the increased parasitic losses. Similarly, when the width of the transistor is kept constant and the number of stages is increased, the efficiency initially increases and then degrades as more number of stages is added due to the increased power loss with additional stages. Coupling capacitor value of 4 pF is selected as it has a very modest impact on the rectifier's efficiency.

[0077] Further embodiments are shown in FIG. **9**C and FIG. **9**D. The embodiment of FIG. **9**C operates in the same way as the embodiment of FIG. **9**B but uses n-type transistors instead of p-type. Accordingly, the solid wired connections to the gates of the transistors in the main chain are to the right instead of to the left. FIG. **9**D is an embodiment in which the connections to the gates of the transistors of the main chain are each controlled by two transistors. However, unlike in FIG. **9**A, one of these two transistors is p-type and the other is n-type. This allows the gates of these two transistors to be controlled by the same voltage, here using a line connecting to the junction to the right of the corresponding main transistor, and have at most one of the transistors ON at any given point in the input cycle. In addition, the transistors in the main chain are n-type in FIG. **9**D, whereas the transistors of the main chain are p-type in FIG. **9**A. However, either of the embodiments of FIG. **9**A or FIG. **9**D could use n-type or p-type transistors in the main chain, with corresponding changes to the direction of connections as seen in the differences between FIG. **9**B and FIG. **9**C. FIGS. **9**C and **9**D don't show the additional transistor at the end of the rectifier that is shown as M_{n+1} in FIGS. **9**A and **9**B, but such an additional transistor may also be present in these figures. The additional transistor can be p-type or n-type.

[0078] To investigate the effectiveness of the adaptive blocks in reducing the leakage current, leakage current as a function of input power is plotted as shown in FIG. **11**A. The leakage current is simulated for the last transistor with a 1 MΩ load for different input power levels. As shown in FIG. **11**A, comparing the schemes i.e. hybrid, adaptive solid and adaptive diode-connected for power levels of 1 μW-100 μW and at an operating frequency of 915 MHz, the reverse leakage current is maximum for the hybrid scheme and increases with the input power. At an input power of 105 μW, the leakage current is 12 nA. The adaptive solid and the adaptive diode-connected scheme have an auxiliary transistor to control the reverse leakage current. At an input power of 1 μW, the auxiliary transistor does not have enough input power to turn ON and provide the required forward-compensation. Hence the leakage current is comparable with the hybrid scheme. At 1 μW (−30 dBm), the output transistor's leakage current is 6.96 nA for the adaptive solid scheme and 7.56 nA for the adaptive diode-connected scheme with a 1 MΩ load. As the input power increases, the leakage current for the adaptive scheme is drastically reduced as seen in FIG. **11**A. Also, the reverse leakage current for the adaptive schemes is relatively constant with increase in the input power. The leakage current also depends on the load resistance and increases with decrease in the load resistance. Another performance measuring parameter we have defined is the current transfer ratio which is the ratio of the forward-current to the reverse leakage current. FIG. **11**B shows the current transfer ratio as a function of input power. The current transfer ratio at an input power of 1 μW (−30 dBm) for the hybrid scheme is 270, for the adaptive solid scheme is 140 and for the adaptive diode-connected one is 108. The current transfer ratio for the adaptive solid scheme increases rapidly and outperforms the hybrid scheme from 2 μW (−27 dBm) while for the adaptive diode-connected one, the current transfer ratio intersects the hybrid curve at 11 μW. The current transfer ratio for the hybrid scheme initially increases with the input power and saturates to approximately 1500 at 100 μW of input power. The current transfer ratio for the adaptive solid scheme rapidly increases with the input power. At an input power of 90 μW, the current transfer ratio for the adaptive solid scheme is 9000 as shown in FIG. **11**B. The current transfer ratio for the adaptive diode-connected scheme is 4000 at 97 μW of input power. The current transfer ratio for the adaptive-solid scheme at an input power of 100 μW (−10 dBm) is 6 times while for the diode-connected one is 2.5 times better than the hybrid scheme.

[0079] The proposed adaptive scheme is effective in increasing the PCE with the addition of auxiliary adaptive blocks. The increase in the PCE with the addition of the adaptive auxiliary blocks for the adaptive diode-connected scheme is shown in FIG. **12**A. With the addition of the auxiliary block the maximum PCE increases to 12%. The auxiliary block is added for every alternate transistor. However, the additional power consumed by the auxiliary diode-connected transistor when the rectifying device in the main rectification chain is forward-biased prevents the scheme from achieving higher PCEs. Unlike the adaptive diode-connected scheme, the auxiliary adaptive block is added to all the transistors for the adaptive solid scheme. Except for the first and the last stage, all the transistors for the solid adaptive scheme have the adaptive blocks. The additional power consumption and the parasitic capacitance introduced by the auxiliary chain are much lower than the former circuit as the solid-connected scheme uses only one transistor of width 480 nm per adaptive block. Hence the PCE is relatively higher at extremely low power levels. As seen from FIG. **12**B, with the addition of adaptive blocks, the efficiency increases. FIG. **12**B shows the improvement in PCE of the rectifier with the addition of auxiliary block. The maximum PCE reaches to 33.5% when the number of adaptive blocks is 20, a figure much higher than the adaptive diode-connected scheme which has a maximum PCE of 12%. The PCE and the output voltage performance at a relatively higher power level 0 dBm to −20 dBm is much better compared with only the hybrid scheme.

[0080] Impedance Matching Technique

[0081] The overall PCE of the RF energy harvesting system can be improved by increasing the passive voltage amplification due to the matching network, which increases the overall voltage at the input of the rectifier. The rectifier is modeled as $R_{rec}-jX_{rec}$ where R_{rec} is the real part of the rectifier's impedance and X_{rec} is the imaginary part. An impedance matching circuit is designed to match it to 50Ω as shown in FIG. **13**.

[0082] The input capacitance is mainly associated with the parasitic capacitance of the transistors and the layout. As the number of stages increases, the input resistance decreases while the parasitic capacitance increases. Increase in the value of load current also decreases the input resistance. The major factor contributing to increase in load current is lower load resistance. Other factors affecting the input impedance is the aspect ratio (W/L) of the transistors, input power level. Increase in the aspect ratio, increases the parasitic capacitance whereas decreases the input resistance. At the output side, the rectifier can be modeled by a voltage source and an output resistance. Thus the non-linear characteristic of the rectifier circuit makes it difficult to analyze them. The input impedance of the rectifier can be assumed to be constant only when small signal input is applied. In this case, the transient signal is a large signal with a capacitive component at the input causing a phase difference component ϕ to appear. The derivation in appendix though considers the reactive impedance still assumes the linear VI relationship. In real case, the VI relationship is non-linear and the input resistance is to be found using CAD tools.

[0083] Experimental Results—Hybrid Scheme

[0084] Three rectifiers, named as "efficiency", "voltage" and "1-stage PMOS doubler" are designed and fabricated in a 0.13 μm 8-metal CMOS process. The active die areas for efficiency circuit, voltage circuit and the 1-stage PMOS doubler test circuit are 230 μm×810 μm, 230 μm×1050 μm and 160 μm×70 μm respectively. The chip is wire-bonded onto PCB board with FR4 substrate and tested with Agilent MXG-N5181 signal generator at a frequency of 915 MHz using a single-tone sinusoidal signal. The receiver power is calculated by finding the average power at the input of the rectifier. The performance of the designed efficiency and voltage circuit is measured for a range of input power levels.

[0085] Output DC voltage was measured for different peak-to-peak input voltages. For a 1 MΩ load, an input voltage of 170 mV results in 2.4 V and 2.8 V for efficiency and voltage circuit, respectively. The voltage multiplication ratio (VMR) which is the ratio of DC voltage to the peak-to-peak input voltage is 14 and 17 for efficiency and voltage circuit respectively. A 220 mV signal results in 3.1 V for efficiency circuit and 4.0 V for voltage circuit. Similarly for a 5 MΩ load, an output of 2.7 V (VMR=16) for efficiency circuit and 3.0 V (VMR=18) for voltage circuit was measured at an input peak-to-peak voltage of 170 mV. Thus, voltage circuit which has a higher level of compensation than efficiency circuit has a lower input voltage requirement.

[0086] Harvested power was measured for different received powers. From the results, it was observed that at low power-level, the harvested power has a higher dependence on load current. For a 1 MΩ load at power levels greater than −30 dBm, the rate of decay in the harvested power curve is higher than the 5 MΩ load. The roll-off in the harvested power for a 1 MΩ load starts at about −20 dBm while the roll-off point for a 5 MΩ load is approximately −30 dBm. Even for voltage circuit, the rate of decay in the harvested power curve is greater for a 1 MΩ load compared to a 5 MΩ load. A lower load value has a higher current requirement. The performance of both the circuits in terms of roll-off is similar for the same load value. The designed efficiency and voltage circuit outperforms the circuit in Papotto et al. especially at low power levels. The efficiency circuit delivers an output power of 4.7 μW at an input power of −16.8 dBm (20.9 μW) when loaded by 1 MΩ. With a 5 MΩ load, the output power is 1 μW for an input power of −17.5 dBm (17.7 μW). An output power of 3.4 μW at an input power of −14.8 dBm (33.1 μW) for a 1 MΩ load is supplied by voltage circuit. A graph of the measurements was found to be in close agreement with the simulation results.

[0087] Power efficiency was measured for different received power levels. The measured and the simulated power conversion efficiency for efficiency and voltage circuit for different load resistance values are further compared. The efficiency comparison is done while de-embedding the input reflections in Papotto et al. The output DC voltage was also measured for the efficiency and voltage circuits for different load resistance values. The PCE is optimized for low power levels. When loaded by 1 MΩ, efficiency circuit attains a maximum measured PCE of 22.6% at −16.8 dBm (20.9 μW) while delivering 2.2 V to the output. A maximum measured PCE of 21.6% is obtained by efficiency circuit while producing an output voltage of 1.1 V at an input power of −26.5 dBm (2.23 μW) for a 5 MΩ load. At an input power level of −14.8 dBm (33.1 μW), voltage circuit achieves a maximum measured PCE of 10.2% for a 1 MΩ load while delivering 1.8 V. Due to a lower load current requirement for a 5 MΩ load, the output voltage is higher compared to a 1 MΩ load. At an input power of −22.5 dBm (5.6 μW), voltage circuit has a measured output DC voltage of 1 V while efficiency circuit has a measured output DC voltage of 1.8 V at −24 dBm (4 μW) for a 5 MΩ load.

[0088] Experimental Results—Adaptive Scheme

[0089] Three RF-DC power converters named as "adaptive solid," "adaptive diode-connected" and the "hybrid" circuits were designed and fabricated side by side in a 0.13 μm metal CMOS process with eight layers of metallization. The active die areas for adaptive solid and adaptive diode-connected is 0.25 mm^2 and hybrid circuit is 0.15 mm^2. The chip is wire-bonded onto a 2-layer FR-4 PCB board and tested with Agilent MXG-N5181 signal generator using frequency modulated continuous signal in the 902-928 MHz industrial, scientific and medical (ISM) band. An off-chip L-section impedance matching network is implemented on the PCB to convert the RF-DC power converter's input impedance to 50Ω. The output DC voltage was obtained with an oscilloscope or a digital multimeter. The measured and the simulated PCE for the adaptive and the hybrid scheme were compared for a load resistance of 1 MΩ at different input power levels. The output DC voltage was measured for the adaptive and the hybrid scheme for a load resistance of 1 MΩ. The simulation is performed at a frequency of 915 MHz which is the center frequency for the 902-928 MHz ISM band. The adaptive RF-DC power converters are designed to provide high PCE and a large output DC voltage for input power levels of 1 μW-100 μW (−30 dBm to −10 dBm). At larger input power, even with lower PCE the available output power is large hence designing for high input power levels is not so crucial. The adaptive solid scheme attains a maximum PCE of 32% at an input power of 32 μW (−15 dBm) with an output DC voltage of 3.2 V for a 1 MΩ load. For the input power of 32 μW and 1 MΩ load, the hybrid scheme has a PCE of 18% and delivers 2.6 V to the output. The adaptive diode-connected scheme has a maximum PCE of 11.3% at an input power of 118 μW while delivering 3.7 V to the output. The additional power consumed by the auxiliary diode-connected transistor when the rectifying device in the main rectification chain is forward-biased prevents the adaptive diode-connected scheme from achieving higher PCEs. The PCE was measured for different input power for the adaptive solid scheme at different load resistances. The output DC voltage for the adaptive solid scheme was also measured as a function of input power for different load resistances. As the load resistance decreases, the peak conversion efficiency curve shifts towards similar efficiencies at higher input power. The maximum measured PCE is 33.4% for a load resistance of 500 kΩ load at an input power of 83 μW. The PCE for a 500 kΩ load is larger than a 1 MΩ load for input power levels greater than 50 μW (−13 dBm). The peak power conversion efficiency curve is a function of the load resistance and can provide peak efficiency at a much lower power levels for larger load resistances. With decrease in load resistance, the circuit provides a smaller output voltage than with the high load resistance due to the low load current requirement at high load resistances. The hybrid scheme provides a larger output voltage compared to the adaptive schemes for input power levels lesser than 15 μW. The adaptive scheme outperforms the hybrid scheme once the power-up threshold-requirement is met. A DC output voltage of 3.2 V is obtained at an input power of 64 μW (−12 dBm) for a 500 kΩ load.

[0090] The harvested power was measured as a function of input power for the adaptive and the hybrid scheme. When loaded by 1 MΩ, an output power of 10 μW is harvested with an input power of 250 μW (−6 dBm) for the hybrid scheme while the adaptive solid scheme harvests 10 μW with only 30 μW (−15.3 dBm) of input power. With a load resistance of 500 kΩ, 10 μW of output power is harvested at an input power of 42 μW (−13.8 dBm). An output power of 20 μW is harvested at an input power of 64 μW (−12 dBm) for a 500 kΩ load using adaptive solid scheme. For a 1 MΩ load, at larger input power, the PCE degrades much more rapidly compared to a 500 kΩ load. For a 1 MΩ load, 20 μW of power is harvested by the adaptive solid scheme at 164 μW (−7.9 dBm). Even with an input power of few milliwatts, the hybrid scheme is not effective in harvesting 20 μW of output power.

[0091] The adaptive scheme is highly effective when the input power is above 10 μW (−20 dBm) and a large output voltage (more than 1.5 V) is desired. The performance of the adaptive solid scheme is similar to the hybrid scheme for power levels of 1-10 μW (−30 dBm to −20 dBm). The sensitivity of the RF-DC power converter for obtaining an output voltage of 1 V with a 1 MΩ load for the adaptive solid scheme is 8.9 μW (−20.5 dBm). The sensitivity of the circuit using the hybrid scheme is 6.9 μW (−21.6 dBm). The adaptive diode-connected scheme gives similar performance as the adaptive solid scheme at input power levels greater than 100 μW (−10 dBm). For low power applications, the adaptive solid scheme should be preferred over the adaptive diode-connected scheme.

[0092] The forgoing description pertains to circuitry using MOSFET enhancement-mode transistors. Nothing in the description should be taken to exclude using other types of transistors with corresponding changes to the circuitry that would be obvious to a person skilled in the art.

[0093] Immaterial modifications may be made to the embodiments described here without departing from what is covered by the claims.

[0094] In the claims, the word "comprising" is used in its inclusive sense and does not exclude other elements being present. The indefinite articles "a" and "an" before a claim feature do not exclude more than one of the feature being present. Each one of the individual features described here may be used in one or more embodiments and is not, by virtue only of being described here, to be construed as essential to all embodiments as defined by the claims.

APPENDIX

[0095] In section II, the average input power was suggested consisting of real and imaginary parts.

$$V = V_{in}\sin\omega t,\ I = I_{in}(\sin\omega t - \phi)$$

$$P_{mean} = \frac{1}{T_2 - T_1}\int_{T_1}^{T_2} V_{in}\sin\omega t \cdot I_{in}(\sin\omega t - \phi)dt$$

$$Z_{in} = \frac{V_{in}^2}{2P_{mean}} \cdot \cos\phi + \frac{V_{in}^2}{4P_{mean}} \cdot \frac{\sin[2\omega(T_2 - T_1) - \phi]}{\omega(T_2 - T_1)}$$

[0096] Z_{in} consists of real and imaginary component. Equating the imaginary component to zero by considering the phase difference $\phi=0$.

$$R_{in} = \frac{V_{in}^2}{2P_{mean}},\ C_{in} = \frac{4P_{mean}(T_2 - T_1)}{V_{in}^2\sin[2\omega(T_2 - T_1) - \phi]}$$

1. A power conversion circuit comprising:

a first input line and a second input line, the first and second input lines configured to receive an alternating voltage differential between the first and second input lines;

a multi-stage rectifier comprising transistors arranged in series, each transistor having a gate, a source and a drain, adjacent transistors of the series being connected so that for adjacent p-type transistors the drain of the left p-type transistor is connected to the right adjacent source of the right p-type transistor and source of the right p-type transistor is connected to the left adjacent drain of the left p-type transistor, for adjacent n-type transistors the source of the left n-type transistor is connected to the right adjacent drain of the right n-type transistor and drain of the right n-type transistor is connected to the left adjacent source of the left n-type transistor, for a p-type transistor adjacent to an n-type transistor the source of the right p-type transistor is connected to the source of the left adjacent n-type transistor and drain of the left p-type transistor is connected to the drain of the right adjacent n-type transistor to form a junction, each junction being connected to one of the first input line and the second input line via a capacitor, with adjacent junctions having one junction of the adjacent junctions connected to the first input line and the other junction of the adjacent junctions connected to the second input line;

the gate of each transistor of the multi-stage rectifier being connected to a respective junction that is not a junction formed by the connection of that transistor to an adjacent transistor but a junction in the previous stage for the p-type transistor or later stage for the n-type transistor, at least one of the transistor in the multi-stage rectifier being p-type and at least one being n-type.

2. The power conversion circuit of claim **1** further comprising an auxiliary chain of p-type transistors, each auxiliary transistor having a gate, a source and a drain, each transistor of the auxiliary chain being connected to a p-type transistor of the multi-stage rectifier in the main chain, so that the gate of the respective auxiliary transistor is connected to the source of the respective transistor in the main chain, the source of the respective auxiliary transistor is connected to the gate of the transistor in the main chain and also connected to the previous stage junction of the main chain which is N transistors away from the respective transistor, and the drain of the respective auxiliary transistor is connected to the drain of the respective transistor or to the junction of the later stage transistor in the main chain.

3. The power conversion circuit of claim **1** further comprising an auxiliary chain of n-type transistors, each auxiliary transistor having a gate, a source and a drain, each transistor of the auxiliary chain being connected to an n-type transistor of the multi-stage rectifier in the main chain, so that the gate of the respective auxiliary transistor is connected to the source of the respective transistor in the main chain, the source of the respective auxiliary transistor is connected to the gate of the transistor in the main chain and also connected to the later stage junction of the main chain which is N transistors away from the respective transistor, and the drain of the respective auxiliary transistor is connected to the drain of the respective transistor or to the junction of the previous stage transistor in the main chain.

4. An auxiliary chain of transistors, each auxiliary transistor having a gate, a source and a drain, each transistor of the auxiliary chain being connected to a respective transistor of a main chain of a multi-stage rectifier in the main chain, so that the gate of the respective auxiliary transistor is connected to the source of the respective transistor in the main chain, the source of the respective auxiliary transistor is connected to the gate of the transistor in the main chain and also connected to the later stage junction of the main chain which is N transistors away from the respective transistor in the case that the respective transistor is n-type, or to the earlier stage junction of the main chain which is N transistors away from the respective transistor in the case that the respective transistor is p-type, and the drain of the respective auxiliary transistor is connected to the drain of the respective transistor or to the junction of a previous stage transistor in the main chain, in the case that the respective transistor is n-type, or to the junction of a later stage transistor in the main chain, in the case that the respective transistor is p-type.

5. The power conversion circuit of claim **4** in which the transistors of the main chain and auxiliary chain are n-type and further comprising a p-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of later stages, such that the gate of the additional p-type auxiliary transistor is connected to the gate of the n-type auxiliary transistor and the source of the n-type and p-type auxiliary transistors are connected, and the drain of the p-type auxiliary transistors is connected to junction of the main chain which is at 'N' later stages from the respective transistor.

6. The power conversion circuit of claim **4** in which the transistors of the main chain and auxiliary chain are p-type and further comprising an n-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of earlier stages, such that the gate of the additional n-type auxiliary transistor is connected to the gate of the p-type auxiliary transistor and the source of the n-type and p-type auxiliary transistors are connected, and the drain of the n-type auxiliary transistors is connected to junction of the main chain which is at 'N' earlier stages from the respective transistor.

7. The power conversion circuit of claim **2** further comprising a diode connected transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of previous stages which is N transistors away from the respective transistor.

8. The power conversion circuit of claim **3** further comprising a diode connected transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of later stages which is N transistors away from the respective transistor.

9. The power conversion circuit of claim **4** further comprising a diode connected p-type or n-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of later stages which is N transistors away from the respective transistor.

10. The power conversion circuit of claim **4** further comprising a diode connected p-type or n-type transistor on a line connecting the gate of each transistor in the main chain of the multistage rectifier to the junction of earlier stages which is N transistors away from the respective transistor.

11. The power conversion circuit of claim **1** further comprising an additional transistor connected in series with the multistage rectifier, the additional transistor having a gate, a source and a drain, the gate of the additional transistor being connected to the drain of the additional transistor.

12. The power conversion circuit of claim **1** in which the gate of each transistor in the main chain is connected to the junction of previous stages for p-type transistor and later stages for n-type transistor.

13. The power conversion circuit of claim **12** in which N of the transistors in the multistage rectifier arranged in series are n-type and all but N of the transistors in multistage rectifier arranged in series are p-type.

14. The power conversion circuit of claim **1** in which the second input line is grounded.

15. The power conversion circuit of claim **1** in which the body terminal of each p-type transistor is connected to the respective drain and the body terminal of each n-type transistor is either grounded or connected to the respective drain terminal.

ABSTRACT OF THE DISCLOSURE

A combined antenna and conversion mechanism for reception of beamed high frequency electromagnetic energy in space including a large array of unidirectional current semiconductor rectifier devices. A self-supporting space vehicle utilizing the rectified DC electrical energy for propulsion is disclosed in an illustrative embodiment.

The present invention relates in general to the transfer of energy by means of an electromagnetic wave beam and more particularly to interception and rectification of such energy into low frequency electrical DC energy with a high degree of efficiency.

Improved technology in the field of microwave energy generation at superpower levels has resulted in the realization of electrical energy transmission over considerable distances for remote energization of devices or vehicles without the aid of wires. The transmission of microwave electromagnetic energy into space has been commonly employed in the radar pulse echo systems for the detection and orientation of desired objects within a predetermined scanning range of a transmitting antenna. Beams of a similar nature may now be employed for other useful purposes and the advantages attendant the utilization of electromagnetic energy in the microwave region in contrast with other wavelengths may now be enumerated.

Microwaves have been generally defined as high frequency radio waves whose wavelength is less than 30 centimeters, with a lower wavelength limit on the order of 1 millimeter sometimes being applied to what is commonly referred to as the "microwave region." The superiority of high frequency microwaves is due in part to the fact that it is generally desirable to focus the transmitted energy so as to achieve a high power density at a remote point or area with respect to a given power source. In accordance with the laws of optics, the sharpness of the microwave beam produced by a transmitting antenna varies as the ratio of antenna dimensions to the wavelength of the transmitted energy. Therefore, for a given or desired power density or beam sharpness, a decrease in the wavelength of the transmitted energy permits a corresponding decrease in the dimensions of the antenna. From the standpoint of mechanical considerations, it is desirable to employ small antennas and other components, and it is therefore advantageous to employ high frequency energy of very short wavelength. In addition, the difficulties encountered in long wave transmission as a result of natural and man-made interference or noise do not occur with any appreciable significance at microwave frequencies. Further, in aerospace applications with considerable distances separating the transmitter at an earth or mother planet location and the employment of shorter wavelength beamed energy is preferred since longer wave signals will generallly be reflected at certain altitudes by reflecting layers in the atmosphere.

In view of certain losses due to absorption which may occur in the atmosphere, microwaves in the region having the approximate bounds of 2 and 30 centimeters are readily adaptable to the convenient radiation of power to remote points without the utilization of wires. The preferred wavelengths are of the order of 5 or 10 centimeters to provide efficient focusing with existing transmitting antenna systems which may be maintained at a reasonable size. An illustrative device of the superpower high frequency microwave generators operative in the desired band is the so-called Amplitron which is an amplifier having a broad bandwidth and excellent performance characteristics for the focusing of the beam. Such devices are capable of producing 15 or 20 kilowatts of average continuous wave power in the neighborhood of 10 centimeters in wavelength with capabilities expected in the region of 500 kilowatts or more average power with 50 megawatts peak power. A complete description of such devices may be had by referring to Patent No. 2,933,723 issued Apr. 19, 1960 to William C. Brown and assigned to the assignee of the present invention.

With microwave energy capable of being generated and directed over longer distances conversion of such high frequency electromagnetic energy is of paramount concern. One conversion mechanism in the prior art involves direct conversion of such energy into heat which may then be utilized directly or indirectly for propulsion or generation of flight-producing forces. Examples of such devices for heat energy exchange as well as space vehicles utilizing such energy may be noted in Patent No. 3,174,705, issued Mar. 23, 1965, to D. Schiff et al., as well as U.S. Letters Patent No. 3,083,528, issued Apr. 2, 1963 and No. 3,114,517, issued Dec. 17, 1963, to William C. Brown. The heat exchanger method of conversion of electromagnetic energy into useful power is limited by the overall efficiencies of approximately 25 percent in the conversion of heat into mechanical or electrical work. Desirable, therefore, would be the direct rectification of the high frequency electromagnetic energy into low frequency electrical energy for the operation of many useful aerospace devices as well as systems.

The present invention has for its primary object the conversion of high frequency electromagnetic energy in the microwave region directly into low frequency electrical energy.

A further object of the present invention is the provision of a combined nondirectional receiving antenna and microwave electromagnetic energy to low frequency electrical energy conversion means in a unitary structure.

A still further object of the present invention is a provision of a new and novel combined nondirectional receiving antenna and microwave to DC energy converter for aerospace applications.

Another object of the present invention is the provision of a new and novel nondirectional receiving antenna and microwave to DC energy converter having a high degree of efficiency.

Still another object of the present invention is the provision of a new and novel aerospace vehicle with nondirectional receiving antenna and microwave to DC energy converter means with said vehicle being capable of being supported by its own energy generation means at a distance spaced apart from the power generation means.

In accordance with the teachings of the present invention, the above and other objects are achieved by the employment of efficient unidirectional microwave power rectifiers and dipole antenna means. Such rectifying devices, while being individually limited in power-handling capabilities, normally in the order of fractions of watts, have been found to be highly efficient means for the rectification of microwave power when assembled in large numbers in various arrays. It is interesting to note that the observed collective efficiency was on the order of 40 to 70 percent. In an illustrative embodiment, point-

contact semiconductor diodes were arranged in four arm bridge connected networks with the networks interconnected in various configurations such as series, parallel and series-parallel.

In discussing aerospace applications, an additional problem is encountered in the beaming of microwave energy to a remote point and the interception and utilization of such electrical energy. In such applications the advantages of a vehicle which may be maintained in space for indeterminate periods of time without employing a local fuel source are readily apparent. Such devices could readily provide communication networks, surveillance functions using radar techniques along with numerous other functions. The acapture of the beamed high frequency electromagnetic energy raises the need for an efficient antenna means capable of intersecting the beam at high altitudes. Conventional techniques employed in microwave radar usage such as receiving antenna horns are capable of intersecting only a small portion of the beam energy and add considerable weight in applications involving heavier-than-air vehicles. In an exemplary embodiment of the invention a space vehicle, namely a helicopter, is disclosed for either moving flight or a stationary location with self-supporting electrically operative propulsion means. The semi-conductor diode rectifier arrays have been demonstrated to fulfill the receiving antenna functions as well as the electrical energy rectification means in a highly efficient manner. Such combined antenna and rectifier means has also assisted in reduction of the weight problem in airborne devices. Further, it has provided a nondirectional means for the interception of the microwave energy to thereby reduce the problems of focusing inherent in prior art directional horn type receiving antennas.

With the above features, advantages and objects in mind the invention will now be described by reference to the following detailed description together with the accompanying drawings in which:

FIG. 1 is a perspective view of an illustrative diode rectifier;

FIG. 2 is a schematic circuit diagram of a bridge connected diode network with dipole antenna means;

FIG. 3 is a schematic circuit diagram of a plurality of bridge connected networks arranged in series;

FIG. 4 is a schematic circuit diagram of a parallel bridge connected network array;

FIG. 5 is a perspective view of an illustrative embodiment of a combined antenna and rectifier array in a folded or rolled up configuration;

FIG. 6 is a schematic circuit diagram illustrating the bridge connected diode array incorporated in the aerospace vehicle shown in FIG. 7;

FIG. 7 is a schematic representation in elevation illustrative of a heavier-than-air aerospace vehicle incorparating the structure of the present invention;

FIG. 8 is a perspective view of the aerospace vehicle embodiment as viewed from the under portion thereof; and

FIG. 9 is an enlarged partial view in elevation of a portion of the illustrative embodiment shown in FIG. 8.

FIG. 1 illustrates a point-contact semiconductor diode rectifier of the type employed in radar microwave receiver apparatus to rectify returned radar pulses. Any of the high burnout semiconductor diodes having high rectification characteristics are preferred and are commercially available, such as the 1N82 or 1N830. The rectifying junction is formed by whisker element **2** contacting the semiconductor element **4** respectively connected to leads **6** and **8**. Silicon is preferred over germanium for element **4** because of its ability to operate at higher temperatures and thereby handle higher powers. Envelope **10** houses the rectifying elements and may be of a hermetically sealed dielectric material or combination metal and ceramic composition. The inherent characteristic of such diode rectifiers is that the microwave energy is intercepted and rectified in a unidirectional manner and the line **11** indicate pictorially the rays of the beamed electromagnetic microwave energy in a plane normal to the envelope. In FIG. 2 a full-wave bridge connected diode network is illustrated with the forward direction of the rectified DC electric current indicated by the direction of the arrow symbols. The network shown consists of half-wave dipoles **20** and **22** each terminated with a diode rectifier element **24** to **27** in an arm of the bridge connected network. The dipole elements **20** and **22** are of the half-wave configuration and may be spaced apart from each other a one-half wavelength at the frequency of the beamed electromagnetic energy.

Referring now to FIG. 3, an array of bridge connected diode networks each with the half-wave dipoles are shown connected in series. Each network is referred to by the numeral **30** and is similar in the bridge connections to the single element network shown in FIG. 2. The DC output of the collective rectified energy is coupled by means of terminals **32** and **33**. In FIG. 4, a similar number of individual bridge connected diode-dipole networks are shown connected in a parallel array. Each network is indicated by the numeral **40**, and the output terminals are indicated as **41** and **42**.

Any number of diode-dipole networks may be provided and in FIG. 5 such a multi-element array is illustrated by mounting on a flexible material **50** which may be rolled or folded into any desired package or enclosed within a capsule to be launched and released at a predetermined point in space. Any flexible material which is pervious to electromagnetic energy is preferred. The total power desired would be the determining factor in a number of individual diode-dipole elements required. In this embodiment, the bridge connected networks **51** are connected in parallel to the output load indicated by terminals **52** and **53**, and representative measurements of electrical characteristics have shown that approximately five watts of DC electrical energy is realizable for each square foot of area of the combined antenna-rectifier. While the dipole elements **54** have been indicated in a particular array, it is within the scope of the invention to stagger the placement of such dipoles to increase the over-all efficiency of the antenna-rectifier.

To further increase the DC powder output, the full-wave bridge connected networks are preferably arranged with a plurality of diodes in series in each arm of the bridge. An illustrative schematic circuit diagram of such a configuration is shown in FIG. 6 wherein seven diodes **60** are shown in each arm of the bridge circuit and are connected in series for a total of twenty-eight diodes in each bridge network. The dipole members will then be the substantially U-shaped end portions **61** at the ends of each brace of seven diodes. In the illustration three such twenty-eight diode bridge networks are shown connected in parallel to terminals **62** and **63**. This closer spacing and compact arrangement has been shown to be a source of improved power output and is capable of a high degree of reliability through the redundant nature of the parallel series connections within each bridge network. If one of the diode rectifiers fails to function the over-all voltage drop across this element would be divided among the six remaining diode rectifiers. If any of the connecting wires between the diode elements should break, the adjacent arms of the other bridge assemblies would take the additional load due to the close proximity of the respective arms to each other. In addition, it is possible to have a number of open connections or inoperative diodes dispersed throughout the array without any serious impairment in performance.

In relation to the array concept to be hereinafter described it may be stated that within a six inch square area ten such individual bridge networks each containing twenty-eight diode rectifiers for a total of 280 diode rectifiers may be deployed in such a manner as to provide

maximum exposed area for each diode as well as the connecting leads. Such an arrangement will be hereinafter referred to as a "module" and a DC output in excess of fourteen watts has been measured for such a module. Any number of such modules could be connected provided for a desired power yield and this module concept readily lends itself to use in certain aerospace applications now to be described.

In FIG. 7 a propelled type of space vehicle **70** is shown wholly supported by means of the transfer and rectification of continuous wave electromagnetic energy via a microwave beam **72**. The source of the microwave energy which may be of the Amplitron type device as described in the aforementioned issued Patent No. 2,933,723 is indicated as **74**. This energy is fed by waveguide means **76** to a transmitting horn **78** to illuminate an ellipsoidal beam forming focusing antenna **80** for the transmission of the microwave beam **72**. It will be appreciated by those skilled in the art that the representations of the microwave generation and transmitting antenna means are pictorial representations to illustrate the usage of the invention in diagrammatic form and the present invention is not limited to any particular source of microwave energy or transmitting antenna assembly. It may be stated the reflector of the antenna assembly is considerably larger than most of the reflectors of the prior art in order to focus a large amount of the microwave power at high altitudes for use in the transfer of energy to space vehicles. Such antenna assemblies may be partially supported in a large hollowed area on the earth's surface or other convenient means of support.

The space vehicle or helicopter **70** can be described as a main body member supporting antenna-rectifier means **82** including a large number of the so-called modules connected together and rigidly supported in a planar parallel array. A motor **84** is supported by the combined body member and the receiving antenna-rectifier means and actuates the rotor **86** of conventional design employed in such self-propelled hovering vehicles. The disclosed vehicle provides for the illumination of the planar array of the semiconductor diode dipole elements by the microwave beam and the direct conversion of the microwave power transmitted by the beam into usable electrical energy for the self-propulsion of the device without any local fuel supply being required.

FIGS. 8 and 9 illustrate a space vehicle **82** comprising a plurality of the combined receiving antenna-rectifier module means for interception and rectification of the electromagnetic microwave energy beam emanating from an earth or mother planet source. A planar array of the antenna-rectifier modules is mechanically supported by means of structural members **90** of any lightweight wood or metal. Insulators **91** positioned coextensive with the members **90** support the diode rectifier array and avoid interference with the receiving and electrical performance characteristics by the structural support members. Carrying forward the module concept of 280 diode rectifiers to provide an approximate power output of 14 watts, it was noted that any number of such modules may be coupled together since the individual module outputs are relatively insensitive to a wide range of load resistances connected to the common output terminals. To achieve the desired electrical output of approximately 120 volts and 250 watts of power, subgroups of four modules each were assembled and parallel connected with an approximate 30 volts available for each subgroup. Four such subgroups were series-connected to result in a total of 4,480 diode rectifiers or 16 modules assembled in a two foot square self-supporting planar parallel array structure. The individual diode rectifiers connected in each arm of the bridge network are indicated by the numeral **92**. An exemplary module configuration would extend within the area delineated by the dotted lines and reference letter A on one side and similar dotted lines and reference letter B on the other side.

A motor **94** is connected to the DC side of the overall array and may be additionally supported by tubular member **95**. A shaft and propulsion means consisting of rotor blades **97** provide for the upward lift of the overall vehicle for the self-supporting of same in space applications. Additional structural support such as interlaced rigging **96** of a high tensile strength material such as nylon or steel wire, as well as bracing member **98**, may be employed for strengthening of the body means to withstand the vibrational forces and downwash from the propulsion means.

In accordance with the well known technology of microwave transmission the combined array of diode rectifiers and propulsion means presents a specific load impedance which must be suitably matched to the transmitted microwave energy beam to result in maximum efficiency. In aerospace applications a mismatch of approximately ten to one may be evident. Matching of the load impedance to a value of approximately 377 ohms as the free space value will be provided by a plurality of coplanar parallel metallic rod members **99** disposed in a grating array in front of the diode rectifiers a predetermined distance. Rod members **99** are linearly disposed and extend in a similar direction as the assembled diode rectifiers. A selected frontal spacing of one-quarter of the wavelength of the microwave frequency being transmitted has been experimentally determined to be suitable for impedance matching purposes. An approximate spacing of two inches between the respective members was preferred for a selected microwave frequency of 2,450 megacycles. Each of the members **90** are provided with lateral sections **100** to support the elongated bar members **101** which in turn maintain the rod members **99** in the desired position. A tubular member **102** of a lightweight metal may also be provided to combine with the motor support member **95** for structural support.

The combined antenna-rectifier array provides a source of electrical energy to render any space vehicle self-supporting. The diode rectifier elements when assembled in the antenna array have been found to be nondirectional with respect to interception of the beamed microwave energy. This represents a large step forward in the utilization of high power microwave energy over the prior art horn-type receiving antennas which must be accurately focused and pointed in a particular direction for the reception of any energy. The connections between the respective members of the diode rectifier array and deployment in the parallel configuration serves to provide maximum exposed area. Such connections and in particular the end loop portions adjacent the terminus of each arm of the bridge networks serves as an efficient dipole for the interception of the microwave energy.

Although it is not intended as a full explanation of the high degree of efficiency attained with the disclosed antenna-rectifier array, it is believed that the whisker elements within the semiconductor diodes themselves are a contributing factor and may function as additional dipole elements. The disclosed embodiment functioned efficiently when illuminated by microwave energy generating a vertically polarized beam. Hence, an efficient and light weight energy conversion apparatus is disclosed which may be self-supporting without the requirement of a large local fuel supply payload.

It may be within the purview of the invention to use the available rectified electrical energy for performing many functions in addition to the actuation of the propulsion means. Hence, communications' payloads may be maintained at predetermined positions in space in a hovering attitude utilizing a portion of the electrical energy available. Relay signals to other such vehicles or return signals to ground stations would then be within the realm of possibility. Such available energy may also be employed for servomechanisms, stabilizing and countertorque systems for the navigation of such vehicles.

The electrical efficiencies realized with the combined

receiving antenna and rectifier means have also provided certain weight advantages over other energy converters in aerospace applications. Examples of such converters would be heat exchangers or solar cells. In comparison to the present invention where five to eight pounds per kilowatt of energy realized is a normal characteristic, other energy conversion means weigh in the vicinity of 150 pounds per kilowatt of realizable energy. The inherent advantages of the present invention are therefore apparent. While the technology in the diode rectifier art is being continually advanced, new diode power rectifiers as well as integrated circuit techniques are readily available to future configurations of the present invention. The so-called Schottky barrier diodes could be employed to produce combined antenna-rectifier means weighing even less than two pounds per kilowatt of available energy.

Although the foregoing detailed description has referred to DC power rectification it will be evident that with suitable circuit components low frequency AC energy may also be made available. In addition, other propulsion means may be readily substituted using electrical energy. The embodiments disclosed herein are illustrative only and other modifications or alterations will be apparent to those skilled in the art which do not depart from the scope of the broadest aspects of the present invention as defined in the appended claims.

What is claimed is:

1. A space vehicle comprising:
body means;
said body means including spaced structural support members;
combined antenna and DC electrical energy rectification means for the interception and rectification of incident high frequency electromagnetic microwave energy carried by said support members in a planar parallel array;
said rectification means comprising a plurality of four

arm full-wave bridge connected rectifier circuit networks each having a plurality of unidirectional semiconductors in each arm;
said networks being electrically interconnected to common output terminals;
electrically operable propulsion means comprising a motor and rotor members carried by said body means and connected to said terminals for the utilization of said rectified DC energy; and
means for matching the load impedance of said combined antenna and electrical energy rectification means to the incident microwave energy.

2. A space vehicle according to claim 1 wherein said load impedance matching means are arranged in a coplanar array coextensive with said antenna and energy rectification means array, and spaced therefrom a distance of approximately one-quarter of a wavelength at the frequency of the microwave energy.

3. A space vehicle according to claim 2 wherein said load impedance matching means comprise a plurality of parallel disposed elongated metallic members.

[57] **ABSTRACT**

A transponder device receives a carrier signal from an interrogator unit. This carrier signal, of frequeny F, is rectified by a rectifying circuit in order to generate operating power. Logic/timing circuits derive a clock signal and second carrier signal of frequency F/n from the received carrier signal. This clock signal reads a unique identifying data word from a programmable read only memory (PROM). The data word is encoded and mixed with the carrier signal in a balanced modulator circuit. The output of the balanced modulator is transmitted to the interrogator unit where it is decoded and used as an identifying signal. The identifying signal identifies the particular transponder device from which it originated. The rectifier and balanced modulator circuits are realized from the same diode elements. All electrical circuits of the transponder device are realized on the same monolithic semiconductor chip. In one embodiment, an antenna receiving/transmitting coil is also part of the chip, being placed around the periphery thereof. In alternative embodiments, various hybrid elements may be connected to the monolithic elements in order to realize additional functions, such as adjustable tuning of the receiving circuit, independent crystal frequency control, and battery-powered operation.

SINGLE CHIP TRANSPONDER DEVICE

This is a continuation-in-part of copending application Ser. No. 888,246, filed on July 18, 1986.

This invention relates to electronic identification devices and systems, and more particularly to an electronic identification transponder device that is realized with miniaturized circuits built or fabricated on a single monolithic semiconductor chip. This invention also relates to the manner of processing signals within such a transponder device.

BACKGROUND OF THE INVENTION

Electronic identification systems known in the art are generally one of two types: (1) tuned/detuned systems; and (2) transponder systems.

Tuned/Detuned Identification Systems

Tuned/detuned systems are tuned circuits that are selectively detuned by an identification element. (Alternatively, detuned circuits may selectively be tuned by the identification element.) Such systems use a controller/interrogator that sets up some form of magnetic field. This field, when in close proximity to an identification element interacts with the identification element in such a way that the identification element can be identified. For example, in the absence of the identification element, the electromagnetic field created by the interrogator/controller exists in a tuned condition or state. However, as soon as the identification element is brought into close proximity to the field, it interacts with the field in a way to detune it. The manner and degree of detuning can then be measured and used to identify the particular identification element employed. By affixing unique identification elements (those which will interact with the field in a unique way) to a plurality of objects to be identified, such objects can be electronically identified whenever they are brought within the field of the controller/interrogator by simply monitoring the manner and degree of detuning that results. Advantageously, such identification elements may be totally passive, requiring no external or internal power for operation. Thus, they can be realized in a relatively small space. As such, they are especially well suited for use in small, lightweight, inexpensive identification tags that can be placed on the objects to be identified. U.S. Pat. Nos. 3,465,724 and 3,516,575 are examples of such a tuned/detuned electronic identification system.

It is significant to note that the identification element used in such tuned/detuned identification systems does not receive, process, generate, nor transmit any electronic signals. Rather, the identification element merely interacts with the magnetic field created by the interrogator/controller. This interaction can be thought of as a form of magnetic modulation that allows an identification to be made once the field is demodulated.

Because the identification element only interacts with the magnetic field created by the controller/interrogator, and is not required to receive and process any electronic signals transmitted by the interrogator/controller, and is not required to generate and transmit any responsive signals back to the interrogator/controller, the identification element of a tuned/detuned identification system may be realized very inexpensively and compactly. Unfortunately, however, because there are only a limited number of ways that the magnetic field from the interrogator/controller can be modified or modulated, and because the identification element must typically be in very close proximity to the interrogator/controller in order to measurably interact with the magnetic field, such tuned/detuned identification systems are limited in their use. Such systems will typically only be used in applications involving a relatively small number of elements or types of elements that are to be identified. Further, the elements to be identified must be movable to the extent that they can be brought in close proximity to the interrogator/controller.

Transponder Type Identification Systems

A second type of electronic identification system known in the art is the transponder or transceiver system. Such systems employ a transponder or transceiver identification element that is affixed to the objects to be identified. (It is noted that "objects", for purposes of this application and as used hereinafter when referring to items, things, persons, or animals being identified by an identification element of the prior art or the present invention, refers to any thing or item that needs identifying, and includes stationary, movable, inanimate, or animate objects.) This transponder or transceiver element receives an interrogation signal transmitted from a controller/interrogator unit. For purposes of this application, a transponder or transceiver element is any device that receives an incoming interrogation signal and responds thereto by generating and transmitting an outgoing responsive signal. The outgoing responsive signal, in turn, is modulated or otherwise encoded so as to uniquely identify or label the particular object to which the transponder element is affixed.

Because the amount of information that may be contained in the outgoing responsive signal is typically limited only by the type of encoding used, and because modern encoding techniques allow a large amount of information to be included therein, such transponder or transceiver electronic identification systems are especially useful where a relatively large number of objects or types of objects need to be identified. Applicant's U.S. Pat. No. 4,475,481 is an example of such a transponder/transceiver electronic identification system.

Further, because the incoming interrogation signal and the outgoing responsive signal are typically RF signals that have been transmitted from an appropriate RF transmitter circuit, and because such signals can generally be transmitted over further distances than the interactive magnetic field distances associated with detuned/tuned systems, the transponder type identification system is more adaptable to applications where the objects to be identified and the controller/interrogator unit are not necessary in close proximity to each other. (In this application, the term "transponder" will hereinafter be used to mean either "transponder" or "transceiver".)

Unfortunately, because RF transmitter and receiver circuits, as well as encoding and modulation circuits, must be employed within the identification element of a transponder type system, such elements must either carry their own independent power source (e.g., a battery) or must include additional circuitry that allows the needed operating power to be derived from the incoming RF signal. These additional power and circuit requirements have not heretofore allowed the transponder identification element of a transponder type identification system to be realized as inexpensively and compactly as would be desired for many identification applications.

What is needed, therefore, is a transponder type identification element that can be realized inexpensively and compactly in a very small space, thereby providing a transponder type identification system that includes all the advantages of similar prior art transponder type systems, but which eliminates the disadvantages thereof. The present invention addresses this and other needs.

SUMMARY OF THE INVENTION

In accordance with the teachings of the present invention, a very small, inexpensive, reliable transponder device may be realized on a single monolithic semiconductor chip. This chip, in turn, may be incorporated into a very small lightweight tag or label that can be readily and unobtrusively affixed to or carried by movable or ambulatory objects that are to be identified. Such tags or labels may thus function as the identification element of a transponder type identification system as described above.

Advantageously, because the transponder device of the present invention may be realized on a single semiconductor chip, the entire transponder identification element may be packaged in a housing that is much smaller than any similar elements heretofore available. Thus much smaller size opens the door to electronic identification applications not previously possible. For example, in accordance with one embodiment of the invention, the entire transponder device, including its receiving and transmitting antenna coil and power circuits, may be realized on a single semiconductor chip. The small size of a semiconductor chip allows it to be affixed to very small articles, such as vials in a chemical or pharmaceutical processing plant, the location, batch, date code, etc., of any individual vial of which can thereafter be electronically monitored.

The transponder device of the present invention includes receiving means for receiving a carrier signal from a controller/interrogator signal; and diode means for: (1) rectifying the received carrier signal in order to generate the operating power for the device, and (2) mixing an encoded data word (used to identify the particular transponder device being interrogated) with the carrier signal. Also included within the circuits of the transponder device are data generating means for deriving a clock signal that is used to extract a unique code word previously stored in a memory element of the device. This unique code word is thereafter appropriately encoded in order to generate the encoded data word that is mixed with the carrier element. The mixing of the carrier signal with the encoded data word creates sum and difference signals that are transmitted through appropriate transmitting means back to the controller/interrogator unit. Either the sum or difference signal thus serves as the responsive signal that is used to uniquely identify the particular transponder device being interrogated.

An important feature of the present invention is the use of diodes to function both as a rectifier circuit *and* as a balanced modulator circuit.

Another important feature of the invention is the ability to generate a clock signal and data word from the incoming carrier signal, thereby obviating the need for additional, bulky, power-consuming oscillator circuits and modulation/demodulation circuits. Frequency stability is maintained by using a crystal oscillator in the controller/interrogator unit to generate the carrier signal. This carrier signal, when received at the transponder device, is then divided by an appropriate integer in order to generate a stable and second carrier clock signal from which the identifying data word may be generated.

Still another important feature of the invention is the ability to realize all of the transponder circuits on a single monolithic semiconductor chip. In one embodiment, even the receiving/transmitting antenna coil is placed around the periphery of the chip, thereby providing a complete, self-contained, single chip transponder device.

The above and other features combine to provide a transponder device that is vastly improved over any prior art devices. For example, because the circuits can be realized on a single semiconductor chip, the transponder function can be realized for a significantly lower cost. Further, because only a single chip is involved, fewer components are needed to complete the identification system assembly, again resulting in reduced cost and significantly enhancing the system's reliability.

Alternative embodiments of the invention contemplate the use of various hybrid elements to complement and enhance the circuits of the single monolithic semiconductor chip. For example, the addition of a hybrid capacitor and/or resistor allows selective tuning of the device's front end circuits to the particular data rate that is employed. Further, the addition of a hybrid crystal and associated elements allows the device to generate its own stable carrier frequency independent of the carrier frequency from which operating power is derived. Also, the addition of a hybrid battery allows the device to be converted into a self-powered beacon device that periodically transmits its identifying encoded data word without the need for the presence of a carrier signal. For applications where longer distance is required, the coil may be separate from the chip and larger than the chip in order to gather more signal strength (power) from the controller/interrogator.

An electronic identification system is realized according to the teachings of the present invention through the use of a controller/interrogator unit and a transponder device carried by each object to be identified. The controller/interrogator unit includes means for generating and transmitting a stable RF carrier signal. The controller/interrogator unit also includes means for receiving a responsive signal back from an interrogated transponder unit. The transponder unit includes the elements above described that permit it to generate the responsive signal in response to receiving the RF carrier signal, i.e., means for receiving the carrier signal, diode means for rectifying the carrier signal in order to generate operating power for the transponder unit and for mixing the carrier signal with an encoded data word in order to generate the responsive signal, clock means for generating a clock signal that is derived from the carrier signal, data generating means for generating the encoded data word in synchrony with the clock signal, and means for transmitting the responsive signal back to the controller/interrogator unit.

Further, in accordance with the teachings of the present invention, a method is provided for processing a received power carrier signal in a transponder device used in an identification system. This method includes the steps of: (a) receiving the carrier signal, (b) rectifying the carrier signal in order to generate operating power for the transponder device, (c) processing the carrier signal in order to produce a clock signal and second carrier signal, (d) generating a unique data word signal using the clock signal, (e) mixing the second carrier with the power carrier signal in a balanced modulator circuit in order to generate sum and difference signals, the balanced modulator circuit being realized from the same components as are used to rectify the incoming carrier signal, and (f) transmitting the sum and difference signals. In the preferred manner of practicing this method, the clock signal is derived from the carrier signal by simply dividing the received carrier signal by an appropriate integer.

BRIEF DESCRIPTION OF THE DRAWINGS

The above features and advantages of the present invention, as well as other features and advantages, will be more apparent from the following more particular description thereof presented in conjunction with the following drawings, wherein:

FIG. 1 is a block diagram of an identification system, and illustrates the interaction between a controller/interrogator unit and a transponder device;

FIG. 2 is a block diagram of the transponder device of FIG. 1;

FIG. 3 is a block diagram of the controller/interrogator unit of FIG. 1;

FIG. 4 is a schematic diagram of the circuits of the transponder device of FIG. 1;

FIG. 5 is a schematic diagram of the front end of the transponder device of FIG. 1, and illustrates the diode bridge circuit that functions as a rectifier circuit and a balanced modulator circuit;

FIG. 5A illustrates some of the signal waveforms associated with the operation of the circuit of FIG. 5;

FIG. 6 is a schematic diagram of the front end of the transponder device of FIG. 1, and illustrates the use of additional hybrid components that can be connected to the transponder device in order to provide selective tuning of the carrier receiving circuits;

FIG. 7 is a schematic diagram of the front end of the transponder device of FIG. 1, and illustrates the use of a hybrid crystal and battery connected thereto in order to provide additional flexibility in its operation;

FIG. 8 is a schematic diagram of the front end of the transponder device of FIG. 1, and illustrates the use of still additional hybrid elements connected thereto in order to provide selective gating with a crystal oscillator to limit data at a high frequency unrelated to the power carrier frequency;

FIG. 9A is a top view of a monolithic semiconductor chip showing a generalized topographical layout of the various types of circuits used within the transponder device; and

FIG. 9B is a cross-sectional view of the chip of FIG. 9A.

DETAILED DESCRIPTION OF THE INVENTION

The following description is of the best presently contemplated mode of carrying out the invention. This description is not to be taken in a limiting sense but is made for the purpose of describing the general principles of the invention. The scope of the invention should be determined with reference to the appended claims.

Referring to FIG. 1 there is shown a simplified block diagram of an identification system. The system includes a controller/interrogator unit 12 and a plurality of transponder devices or units 14, only one of which is shown in FIG. 1. Each object to be identified carrier a transponder an interrogation signal 16 that is received by the transponder unit 14. After receiving and processing the interrogation signal 16, the transponder 14 transmits a response signal 18 back to the controller/interrogator 12. This response signal 18 has encoded therein an identifying data word that is unique to the particular transponder unit 14 from which is originated. Hence, by positioning or placing the transponder units 14 on the objects to be identified, it is possible to electronically identify the people, animals, or other objects being identified.

Referring next to FIG. 2, a block diagram of the transponder unit 14 is shown. The interrogation signal 16 is received by an antenna coil 20. In the preferred embodiment, this interrogation signal is simply an RF carrier signal that is applied to rectifier/balanced modulator circuit 22 and divide/timing logic circuit 24 over signal line 26. Divide/timing logic circuit 24 divides the carrier signal by an appropriate integer n in order to generate a clock signal and second carrier signal, on output signal line 28, having a frequency that is 1/nth of the frequency of the incoming carrier signal. The clock signal drives data generator circuit 30, which circuit generates an encoded data word. This encoded data word is presented over signal line 32 to the rectifier/balanced modulator 22. Also presented to the rectifier/balanced modulator 22, over signal line 34, is a buffered carrier signal. This buffered carrier signal can be either a "squared-up" version of the incoming carrier signal 16, or a modified carrier signal that has a frequency ½ or ¼ of the incoming carrier signal 16. The modified or buffered carrier signal and the encoded data word are mixed in the rectifier/balanced modulator 22 in order to produce sum and difference signals. These signals appear on signal line 26 and are presented to antenna coil 20, from which they are transmitted as the responsive signal 18.

The incoming carrier signal 16 is also rectified by the rectifier/balanced modulator circuit 22 in order to generate the operating power used by the divide/timing logic 24 and the data generator 30. This operating power is distributed to these circuits over power lines 36 and 38, respectively.

In FIG. 3, a block diagram of the controller/interrogator unit 12 is depicted. While the present invention is primarily directed to the transponder unit 14, and not to the controller/interrogator 12, some features of the controller/interrogator 12 enhance the operation of the transponder unit 14. For example, in the preferred embodiment, the carrier or interrogation signal 16 is generated using a crystal oscillator 40 and appropriate transmission circuitry 42, including transmission antenna or coil 44. This action causes the carrier signal 16 to have a very stable frequency. Because of this stable frequency, it is not necessary, in the preferred approach, to incorporate another crystal oscillator in the transponder unit 14.

The responsive signal 18 generated by the transponder unit 14 is received at the controller/interrogator 12 through antenna coil 46 and receiver circuit 48. These components are tuned to the particular frequency expected for this signal, which, as explained above in conjunction with FIG. 2, will be either the sum or difference frequency resulting from mixing the encoded data word signal with the carrier signal. Further, a band pass filter circuit 50 (which may be included within the receiver circuit 48) will further assure that only those frequencies of interest are passed on to the demodulation/decode circuits **52**. At the demodulation/decode circuits **52**, the responsive signal is demodulated and decoded using known demodulation and decoding techniques in order to extract the data word signal included in the responsive signal **18**. This data word signal serves to identify the particular transponder unit from which it originated. It can be stored in data log circuitry **54** and subsequently displayed by data display circuitry **56**. Alternatively, concurrently with the storage of the data word in data log circuitry **54**, the data word may be displayed by data display circuitry **56**, or data may be sent to a central processor for further processing or control.

Hence, from the block diagrams of FIGS. **1–3**, it is seen that in operation the controller interrogator unit **12** generates and transmits the carrier (interrogation) signal **16**. Upon receipt of this incoming carrier signal **16**, the transponder unit **14** generates a second carrier signal modulated by an encoded data word that is mixed with the carrier signal in rectifier/balanced modulator **22**. This action produces the responsive signal **18** that is transmitted back to the controller/interrogator **12**, which responsive signal **18** uniquely identifies the transponder unit **14** from which it originated.

A schematic diagram showing all usable signals brought out to the pins or transponder unit **14** is illustrated in FIG. **4**. This diagram depicts all of the circuits that are included on the single monolithic semiconductor chip, and further shows the nine pins of terminals, labeled **1–9**, that are used to interface with these circuits. While the antenna coil **20** is not included in the diagram of FIG. **4**, it is noted that it too can be included on the semiconductor chip as shown in FIG. **9**.

Still referring to FIG. **4**, it is seen that the circuitry is relatively simple and that not a lot of circuit elements are required. This simplicity, unavailable heretofore in similar transponder devices, makes possible the incorporation of the device as a self-contained unit on a single chip.

Referring next to FIG. **5**, the front end of the circuits of FIG. **4**—principally the rectifier/balanced modulator circuits **22**—will be explained. From FIG. **5** it is seen that the rectifier/balanced modulator **22** is realized with a diode bridge comprising diodes **60**, **61**, **62**, and **63**. The input terminals to this bridge circuit are pins **3** and **6**. An additional diode **65** is inserted between and in series with diodes **61** and **63**. This diode **65** allows the modulated signal, when applied to the rectifier/balanced modulator **22**, to swing more and thereby increase the percentage of modulation. Further resistors R1 and R2 are inserted into the legs of the bridge circuit as shown in order to distribute the current flow in an appropriate manner. In this regard, resistor R3 also serves to proportion the amount of signal current delivered to the divide/timing logic **24** through pin **3**. In the preferred configuration, R1 has a value that is about 1/10th the value of R2, and R2 has a value that is about 1/10th the value of R3. Hence, in operation, most of the signal current delivered through pin **3**, e.g., during a positive half cycle of the carrier signal, passes to the divide/timing logic **24** and not to the bridge circuit portion that includes diode **62**. However, when pin **6** is positive with respect to pin **3**, e.g., during a negative half cycle of the carrier cycle, then most of the signal current passes through diodes **65** and **63** in order to charge the supply voltage.

A zener diode **66** is incorporated into the bridge circuit in order to stabilize the voltage VDD that is generated. In the preferred embodiment, the voltage VDD is around six volts, although any suitable voltage level could be used. The bridge circuit uses the capacitance inherent in all the circuit elements present on the chip to help store the energy needed to maintain a sufficiently constant supply voltage VDD. This capacitance is shown in FIG. **4**, as C1, but it is to be understood that C1 represents all of the distributed and other internal capacitance present on the chip, and is not a separate element. In this regard, the inventor has found that it is not necessary that the voltage supply VDD he maintained at a constant level at all times. It is sufficient, for the type of synchronous operation herein used, if the supply voltage VDD is maintained at a prescribed level only when the circuits are active (i.e., drawing current). For CMOS circuits, such activity only exists during a data transition. Because the operation of the device is essentially synchronous—everything occurs in synchrony with the clock signal, which in turn is in synchrony with the received carrier signal—it is possible for the device to function so long as the requisite VDD voltage is present during the transitions of the carrier signal. Where the frequency of the carrier signal is sufficiently fast, as is the case here, the capacitance C1 doesn't have to hold a charge very long in order for the device to operate. Hence, C1 (which, again, is comprised of all the distributed and internal capacitance on the chip) does not have to be very large in order for the device to operate. It is noted, for example, that the static current drain of a typical CMOS chip is the picoamp range.

Further, even when semiconductor devices other than CMOS circuits are employed, such as TTL or GaAs devices, it is possible for the circuit to function during only a selected half cycle of the carrier signal by setting up the logic circuits so that they only change states during this selected half cycle. Thus, it is possible to design the VDD generation circuitry so that it is primarily charging up during, for example, the negative half cycle of the carrier signal, and design the logic circuits so that they are not active until the positive half cycle of the carrier signal, at which time sufficient charge will be available to provide the needed operating power.

FIG. **5A** illustrates some of the foregoing principles of operation relative to the circuit of FIG. **4** and **5**. In FIG. **5A**, the incoming carrier signal **16** from the controller/interrogator **12** is shown having a frequency Fo. After full-wave rectification, this signal substantially as a dc level having a ripple frequency of 2Fo. A second carrier signal is obtained by dividing the incoming carrier signal by two. This second carrier signal therefore has a frequency of Fo/2. This second carrier signal can, for desired embodiments, be used as a clock signal to generate a data signal, two bits of which, "01", are shown in FIG. **5A**. In turn, this data signal, gated with the second carrier signal Fo/2, is used to modulate the Fo carrier signal, realizing a modulated signal as shown at the bottom of FIG. **5A**.

Also included as part of the rectifier/balanced modulator circuit **22** of FIGS. **4** and **5** is NAND gate **68**. This gate **68** serves to combine the carrier signal (or a derivative of the carrier signal), on signal line **34**, with the encoded data, on signal line **32**, and apply this combination to the diodes **60–63** of the bridge circuit. This action causes these signals to be mixed, resulting in sum and difference frequencies that are presented to the output pins **3** and **6** (and hence to the antenna coil **20**) for transmission to the controller/interrogator **12** or other receiving device.

It is noted that gate **68** of the rectifier/balanced modulator **22** also has a control signal line **70** applied thereto, the function of which is explained below in conjunction with the discussion of FIG. **8**.

Referring next to the divide/timing logic portion **24** of FIG. **4**, it is seen that the incoming carrier signal (received through pin **3**) passes through resistor R3 and inverter gates **72** and **74**. The output of gate **72** is made available at pin **2**, and the output of gate **74** is made available at pin **1**. These pins can be used as explained below in connection with the discussion of FIGS. **6** and **7**.

The output of gate **74** is presented to the clock input of a register **76**. This register **76** divides the carrier signal by an appropriate factor. While the embodiment shown uses a simple series divide-by-2 arrangement, thereby providing outputs that have been divided by 2, 4, 8, 16, . . . , the invention contemplates that other dividing schemes could be employed such that the carrier signal could be divided by any desired integer n.

The desired division of the carrier signal in register **76** provides a clock signal that has a frequency that is 1/nth of the carrier frequency. Included in the divide/timing logic **24** are selection gates **78** that allow the selection of different clock frequencies as controlled by a control signal applied to pin **9**. The selected clock signal is then presented to the data generator circuitry **30** over signal line **28**.

Data generator circuitry **30** includes a programmable read only memory (PROM) array **80** which is accessed through suitable memory control logic elements **82–85**. Elements **82** and **84** are registers through which the clock signal cycles. After a prescribed number of clock cycles, these registers address certain rows and columns of the memory array **80** in order to extract the data that has been previously programmed therein. This data is passed serially to gate **86**, as is the signal Q4 from register **84**. As long as Q4 is high, the extracted data word is allowed to pass out of gate **86**, over signal line **88**, to Manchester encoder circuit **90**. Manchester encoder circuit **90** encodes the data word according to well known Manchester encoding techniques and presents the encoded data word to the rectifier/balanced modulator circuit **22** over signal line **32**. In the preferred embodiment, the encoded word is **64** bits long, although any suitable bit length could be employed. Further, encoding schemes other than a Manchester encoding scheme could also be employed.

The PROM memory array **80** may be realized using any suitable PROM configuration that can readily be incorporated on the same semiconductor chip as are the other transponder circuits. Preferably, an EEPROM (Erasable Electrically Programmable Read Only Memory) device could be used. Advantageously, during manufacture of the chip, or thereafter, the PROM can be easily programmed to contain an appropriate data word that would serve to uniquely identify that particular device. For example, a manufacturing date code in combination with a serial number could be employed for this purpose. If the identifying data word programmed into the device during manufacture did not suit the particular application, this data word could subsequently be erased using appropriate equipment and a new, more suitable, data word could be programmed thereinto.

Also shown in FIG. **4** is a NAND gate **92** and an inverter gate **94**. The inverter gate **94** is connected to pin **9** and is used to condition a control signal applied to pin **9** as discussed below in conjunction with FIG. **8**. The NAND gate **92** has one input connected to pin **7** and the other input connected to the data word signal output from the memory array **80** through gate **86**. The output of this NAND gate **92** is connected to pin **8**. This gate **92** can be selectively connected to additional hybrid elements as discussed below in connection with FIG. **8** in order to provide additional options for using the transponder device.

Referring next to FIGS. **6–8**, schematic diagrams of the front end circuits of the transponder unit **14** are shown, as in FIG. **5**, but further including additional hybrid elements connected thereto through the pin connections provided. In FIG. **6**, capacitor **C2** is connected between pins **1** and **3**, and resistor **R4** is connected between pins **2** and **3**. Further, hybrid capacitors **C3** and **C4** are connected in tandem as shown between pins **4** and **5**, and pins **5** and **6**, respectively. Also, in FIG. **6**, the antenna coil **20** is connected between ground, pin **5**, and pin **6**, in order to disassociate it from interacting with **R4** and **C2**. The values of capacitors **C3** and **C4** are selected as required in order to tune the front end circuit to the particular carrier frequency that is employed. The values of **R4** and **C2** are selected as needed in order to adjust the bit timing. Thus, flexibility is provided in order to make minor adjustments, i.e., tune the circuit, for the particular carrier frequency that is used.

In FIG. **7**, the single chip transponder unit **14** of the present invention is converted to a more conventional transponder unit through the use of a hybrid crystal oscillator circuit, comprising crystal **Y1**, capacitor **C5**, and resistor **R5**, and a battery **B1**. The crystal **Y1** and resistor **R5** are connected across pins **2** and **3**, while capacitor **C5** is shunted from pin **3** to ground (pin **5**). This configuration results in an oscillator circuit comprising the inverter gate **72**, resistors **R3** and **R5**, crystal **Y1**, and capacitor **C5**. This oscillator circuit allows the data word to be generated totally independent of the frequency of any incoming carrier signal. Further, when a battery **B1** is employed, as shown, the transponder device is no longer dependent on the carrier signal, and therefore becomes a transmitting circuit that continually transmits its identifying signal. When a battery **B1** is employed in this fashion, it will typically have a voltage level output that is slightly less than that of zener diode **66**, thereby keeping zener diode **66** turned off and effectively out of the circuit.

In FIG. **8**, a hybrid crystal **Y2**, capacitor **C6** and resistor **R6** are connected as shown to pins **7** and **8** in order to create a crystal oscillator circuit that selectively transmits the data word through a separate antenna **21**. The crystal oscillator is realized with internal-to-the-chip gate **92** and **Y2**, **C6**, and **R6**. Antenna coil **20** still receives a carrier signal and generates VDD therefrom. Further, the frequency of the carrier signal determines the clock rate, which in turn determines the rate at which the data word, appearing on signal line **88**, appears. The crystal oscillator output signal, presented to antenna **21**, is effectively modulated with the data word appearing on signal line **88**. Because gate **92** is only active when VDD is present, the circuit of FIG. **8** can thus function as a responding unit that transmits the data word on a carrier frequency independent of the incoming carrier signal. The use of a control signal applied to pin **9** further disables any signal from being mixed in the rectifier/balance modulator circuit **22**, and hence from being transmitted through antenna **20**, during the time that a signal is being transmitted from antenna **21**. Such a control signal can simply be realized by hardwiring pin **9** to a desired potential.

It is noted that the circuits of FIGS. **6–8** represent only a portion of the various circuit configurations and options that could be realized using the single chip transponder device of the present invention.

FIG. **9A** shows a topographical representation of the transponder chip **14** in an embodiment that includes the antenna coil **20** as part of the monolithic chip. In accordance with this embodiment, the coil **20** is etched or otherwise placed around the periphery of the chip substrate **98**, as described below. In the center of the coil **20** are found a custom logic circuit **100**, a programmable memory array **102**, and memory control logic **104**. Programmable memory array **102**, which may be realized for example from an EEPROM device, comprises the memory array **80** depicted in FIG. **4**. Memory control logic **104** comprises the memory control elements **82–85** of FIG. **4**, and the custom logic circuit **100** includes the balance of the circuitry shown in FIG. **4**. Thus, using the chip topography shown in FIG. **9A**, a functionally complete transponder unit **14** is realized on a single semiconductor chip.

Still with reference to FIG. **9A**, it is noted that placement of the logic circuit **100**, memory array **102**, and memory control logic **104** on the chip substrate **98** can be readily accomplished by those skilled in the art using known hybrid or monolithic circuit fabrication techniques. Not so readily known in the art, is the manner in which the antenna coil **20** is placed on the chip substrate **98**.

One approach for placing the coil **20** on the chip substrate **98** is to make the coil **20** in hybrid fashion, using e.g. a copper conductor, and then bonding the wound coil **20** to the chip using conventional bonding techniques. This approach would advantageously allow the coils to be effectively stacked, if needed, in order to increase the coil inductance without adding stray capacitance.

The preferred approach for placing the coil **20** on the chip substrate **98**, however, is to use a deposition technique that effectively creates a single monolithic chip assembly that includes all of the circuitry necessary to produce a functionally complete transponder unit **14**. While, the prior art teaches that it is extremely difficult to fabricate small air core inductors of sufficiently high inductance and Q for integrated circuit applications, the suggestion is made in the prior art that the use of magnetic film cores for such inductors can reduce the number of turns required, and thereby make the fabrication of such inductors feasible. See Soohoo, "Magnetic Thin Film Inductors For Integrated Circuit Applications", IEEE Transactions in Magnetic, Vol. MAG-15, No. 6, pp. 1803–1805 (Nov. 1979). One technique for using magnetic film cores is described in Salch and Qureshi, "Permalloy Thin-Film Inductors", *Electronic Letters*, Vol. 6, No. 26, pp. 850–852 (Dec. 31, 1970). There it is stated that a 10-turn square spiral coil for use at 10 MHz can be constructed having an outer diameter of 1 cm × 1 cm. The conducting path width is 0.005 inches. The spacing between turns is 0.001 in. The copper path is deposited by vacuum evaporation and then thickness is built up to about 25 micrometers by electroplating. Two permalloy magnetic films, having a thickness of from 1000–3000 Angstroms, surround the conductors, one on top, and the other on the bottom. The film is evaporated in an orienting magnetic field in such a way that the long dimension is parallel to the field, and thus it is the easy direction of magnetisation of the film. When a high-frequency current passes in the coil, the magnetic films are driven in a hard direction, and the two magnetic films around each conductor act as a magnetic core enclosing a 1-turn coil. The effect of the magnetic films is to increase the inductance of the coil in addition to its free-space inductance. The magnetic permeability is quite large, since the films are driven in the hard direction. Further, an insulting silicon-monoxide layer (SiO, 10,000 A thick) separates each magnetic film from the conducting path. For purposes of the present invention, the technique used to place the coil **20** on the substrate **98** is as follows:

(a) a wafer of semiconductor substrate material is processed, using conventional methods and technology, to place the IC circuits in the center of each desired chip area, as shown in FIGS. **9A** and **9B**;

(b) a conductive trace **110** is deposited on the substrate between the regions **112**, **114** (optionally, this step may be included in the fabrication of the circuit of step (a));

(c) a permalloy magnetic film, or other suitable material having a large magnetic permeability and electrical insulating properties, is applied over the wafer, leaving holes for contact to the return trace and the logic circuits at **106**, **108**, **112** and **114**.

(d) the coil **20**, with the exception of the trace **110** (which was previously deposited), is deposited and lithographed using conventional techniques,

(e) contacts are made to the logic circuit **100** through the holes **108**, **106**, and to the trace **110** through holes **112** and **114**;

(f) a second permalloy magnetic film, or other suitable material having desired properties, is applied over the wafer;

(g) the wafer is diced, thereby creating individual chips, each being a fully functional transponder device.

It is noted that the application of the magnetic film, in steps (c) and (f) involves appropriate evaporation (or equivalent techniques) in order to control the thickness thereof, which evaporation may occur in the presence of an orienting magnetic field, as previously described. Thus, this step may involve two sub-steps, a first to place and magnetically orient the magnetic film in a first direction; and a second to place and magnetically orient the film in a second direction (orthogonal to the first direction).

While the invention herein disclosed has been described by means of specific embodiments and applications thereof, numerous modifications and variations could be made thereto by those skilled in the art without departing from the spirit and scope of the present invention. It is to be understood therefore that within the scope of the appended claims, the invention may be practiced otherwise than as specifically described herein.

What is claimed is:

1. A transponder device comprising:

a single monolithic semiconductor chip;

receiving means for receiving a carrier signal from an external source;

diode means for rectifying the received carrier signal in order to generate operating power for the transponder device, and for mixing an encoded data word with the carrier signal in order to generate sum and difference signals;

digital circuit means for deriving a clock signal from said carrier signal;

data generating means responsive to said clock signal for generating the encoded data word that is mixed with the carrier signal in said diode means; and

transmitting means for transmitting the sum and difference signals to a location external from said transponder device;

said diode means, digital circuit means, and data generating means comprising electrical circuits that are realized on said single monolithic semiconductor chip.

2. The transponder device of claim **1** further including a plurality of select hybrid circuit elements and means for connecting said hybrid circuit elements to the electrical circuits of said monolithic semiconductor chip in order to tune said electrical circuits to the frequency of said carrier signal.

3. The transponder device of claim **1** further including a hybrid battery and means for connecting said hybrid battery to the electrical circuits of said monolithic semiconductor chip in order to provide operating power therefor independent of any power contained within said carrier signal.

4. The transponder device of claim **1** further including a hybrid crystal element and means for connecting said hybrid crystal element to the electrical circuits of said monolithic semiconductor chip in order to provide crystal frequency control of the signals used within said electrical circuits independent of the frequency of said carrier signal.

5. The transponder device of claim **1** wherein the receiving means and transmitting means comprise a single antenna coil that is placed around the periphery of the single monolithic semiconductor chip.

6. The transponder device of claim **5** wherein said monolithic semiconductor chip is no larger than 0.01 square inches.

7. The transponder device of claim **1** wherein said diode means comprises a bridge circuit that functions both as a rectifier circuit and a balanced modulator circuit.

8. The transponder device of claim **1** wherein said data generating means includes programmable read only memory (PROM) means, said PROM means having a unique code word previously programmed therein from which said encoded data word is derived.

9. The transponder device of claim **8** wherein said data generating means includes encoding means for encoding the unique code word programmed in said PROM means.

10. The transponder device of claim **9** wherein said encoded data word generated by the encoding means of said data generating means comprises an n bit digital word, wherein n is an integer greater than 7.

11. An electronic identification system for identifying a plurality of objects comprising:

a controller/interrogator unit for interrogating the objects to be identified and processing the responses received, said controller interrogator unit including:

means for generating an RF carrier signal, said RF carrier signal comprising an interrogation signal,

means for transmitting said interrogation signal towards an object to be identified,

means for receiving a responsive signal generated in response to said interrogation signal, and

means for decoding, storing, and displaying the response received; and

a transponder unit, carried by each object to be identified, comprising:

a single monolithic semiconductor chip;

receiving means on said semiconductor chip for receiving the interrogation signal from said controller-interrogator unit,

diode means on said semiconductor chip for rectifying the received interrogation signal in order to generate operating power for the transponder device, and for mixing an encoded data word with a digital carrier signal in order to generate sum and difference signals, said sum and difference signals comprising said responsive signal,

digital circuit means on said semiconductor chip for deriving a clock signal and said digital carrier signal from said interrogation signal,

data generating means on said semiconductor chip responsive to said clock signal for generating the encoded data word that is mixed with the digital carrier signal in said diode means, and

transmitting means on said semiconductor chip for transmitting the responsive signal to said controller/interrogator unit.

12. The identification system of claim **11** wherein the receiving means and transmitting means of said transponder unit include a single antenna coil that is placed around the periphery of said single monolithic semiconductor chip.

13. A transponder device consisting of:

a single semiconductor chip;

receiving means placed on said semiconductor chip for receiving a carrier signal from an external source;

diode means for rectifying the received carrier signal in order to generate operating power for the transponder device, and for mixing an encoded data word with the carrier signal in order to generate sum and difference signals, said diode means comprising an electrical circuit that is fabricated on said semiconductor chip;

digital circuit means for deriving a clock signal from said carrier signal, said digital circuit means comprising electrical circuits that are fabricated on said semiconductor chip;

data generating means responsive to said clock signal for generating the encoded data word that is mixed with the carrier signal in said diode means, said data generating means comprising an electrical circuit that is fabricated on said semiconductor chip; and

transmitting means placed on said semiconductor chip for transmitting the sum and difference signals to a location external from said transponder device.

14. The transponder device of claim **13** wherein the receiving means and transmitting means include an antenna coil that is deposited around the periphery of the single monolithic semiconductor chip.

[57] **ABSTRACT**

A system for transmitting microwaves to one or more receiver assemblies comprises an array of separate microwave transmitting assemblies for emitting a plurality of microwave beams, the array being arranged to apparently fill a radiating aperture of predetermined shape and size when viewed from the direction of a receiver assembly, and a phase controlling assembly associated with the microwave transmitting assemblies for controlling the relative phase of the emitted beams to form at least one composite shaped microwave beam directed to at least one receiver assembly. The receiver assembly is located in the near field of the microwave beam. The transmitting assemblies are each associated with separate power sources comprising solar power collecting assemblies. In one arrangement the transmitting system is on the moon and the or each receiver assembly is on Earth.

POWER COLLECTION AND TRANSMISSION SYSTEM AND METHOD

This application is a continuation of application Ser. No. 07/157,081, filed Feb. 11, 1988, now U.S. Pat. No. 5,019,768, which was a continuation of application Ser. No. 06/732,352, filed May 8, 1985, now abandoned, which was a continuation-in-part of application Ser. No. 06/513,444 of the same applicants, filed Jul. 13, 1983, now abandoned, and entitled "Lunar Power System."

BACKGROUND OF THE INVENTION

The present invention relates generally to the collection and transmission of power, and is particularly concerned with the collection of solar power and its transmission in the form of a microwave beam.

Electric power supplies for most of the earth's inhabitants are currently provided by heat engines (steam turbines or the like) fueled by combustion of fossil fuels (coal, oil and/or natural gas). Progressive exhaustion of readily accessible fossil fuel sources, particularly oil and gas, has led to higher prices, shortages, and prospects for even more expensive and inaccessible fossil fuel supplies in the future.

Renewable energy sources including direct and indirect solar energy systems, the latter including hydroelectric, wind, ocean thermal, photosynthetic fuels (biomass), production of hydrogen and others currently furnish an important but minor fraction of the earth's electric energy. These resources should eventually furnish virtually the entire energy supply unless nuclear fusion energy is rendered economically and technically feasible in the future.

Most of the direct and indirect solar power systems are subject to geographic and climatological limitations. The solar power systems are also subject to variable and unpredictable changes or interruptions of output power. This has necessitated the use of reserve power systems (usually fossil fuel fired) or the use of restrictions on usage to only portions of the daily or long-term power usage cycles. These techniques unfavorably affect the economics of renewable energy use.

Despite these problems, ongoing development work is proceeding for making direct use of solar photovoltaic conversion systems, particularly for locations in latitudes with sunny climates. Current and near-term projected costs of conversion elements are far too high to be competitive with fossil fuel systems, even in the absence of power storage systems associated therewith. Coupled with this is the fact that the most advantageous applications of photoconversion are in economically underdeveloped and isolated regions on earth. There is hope that improvements in engineering and manufacturing methods may lead to systems which are cost competitive with future fossil fuel power systems.

There have been proposals in the past to collect solar power by means of earth orbiting satellites carrying solar collectors, and then to beam the power to suitable rectenna or receiver structures on earth, where the power is stored and distributed to users. Because of the many technological problems involved, none of these systems have yet been put into effect.

One proposal for such a system is described in U.S. Pat. No. 3,781,647 of Glaser, in which an orbiting satellite collects sunlight, converts it into electrical energy, converts the electrical energy to microwaves and beams the microwave power to earth from a planar phased array of microwave transmitters. One problem with this system is that it operates in the so-called "far field" or divergent area of the microwave beam, as is also the case in virtually all radar and high gain communications systems. The radiating near and far field regions of a wave field propagating from a radiating aperture (e.g. antenna) structure are separated by a near field transition length which is approximately equal to $L=D^2/w$ where D is the aperture diameter and w is the wavelength. In the radiating near field in Fresnel region ($L_n<L$), the maximum optical path difference from a field point to the distributed points of the aperture plane exceeds several wavelengths regardless of whether the field point is on or off axis of the system. Under such conditions, the radiated intensity is effectively averaged or smoothed for lateral displacement within the geometric optic beam and rapidly attenuates beyond the beam edge. Thus a beam is produced which closely approximates the geometric optics limit. In contrast, the radiating far field (Fraunhofer) region is divergent and has a maximum optical path difference of less than a wavelength between an axial field point and all points of the aperture plane. The radiated intensity decreases with lateral excursion from the beam center (with or without undulations depending on details of the aperture excitation.

Where an antenna system is used to transmit microwave power from a satellite, as taught by Glaser, the size of the antenna is limited, R is fixed, and the transition length L will be of the order of 10,000 km (for $D=1$ km and $w=10$ cm). Since geosynchronous satellites orbit at 36,000 km, the operating distance is more than three times the near field transition length for the above case. Thus the coherent microwave power of the beam will extend in a lobe-like Fraunhofer diffraction pattern across the earth. Because of the constrains on antenna sizes and operating frequencies for which sufficient atmosphere transparency exists, it would not be practical to operate in the near field in the Glaser system. The minimum beam diameter at the earth receiver would be about 3.6 km, and the approximate beam diameter would be 10 km. Thus the receiver must be very large in order to receive a substantial portion of the power adding considerable expense to the system.

While the Glaser system has certain merit in terms of providing the earth with needed electrical energy, there are major problems associated with the development of such a system. Primarily these considerations are both technological and economic. Technologically, there are many unanswered questions with regard to the feasibility and long term reliability of such terrestrial and space borne power generating systems. There are environmental problems restricting the total power which may be transmitted in this way. Such systems are also extremely expensive.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide an improved system for transmission of microwaves.

It is a further object of the present invention to provide microwave transmission system which operates in the radiating near field where the beam is substantially uniform and at least partially or slightly convergent and can be aimed more precisely at a relatively small receiving or rectenna structure.

According to one aspect of the present invention a microwave transmission system is provided which comprises an array of separate microwave radiators which are arranged to fill a radiating aperture of predetermined size when viewed from a microwave receiver assembly, each radiator emitting a separate microwave beam, a controller assembly for controlling the relative phases of the radiated beams to form a single, shaped composite microwave beam aimed at the receiver assembly, the receiver assembly being positioned in the radiating near field of the composite microwave beam, i.e. at a distance R which is less than about D^2/w where D is the diameter of the effective radiating aperture and w is the wavelength of the microwaves.

Preferably, the microwave transmission system is associated with a solar collector assembly comprising a plurality of solar collectors each associated with a respective one of the microwave radiators. Each collector preferably comprises an array of photoconversion devices and each microwave radiator may comprise an antenna array electrically connected to the collector array via a suitable underground grid, for example. Thus there is no single power source supplying power to all the individual radiators in the array, but there are a plurality of subassemblies each comprising a solar collector, a converter for conditioning and converting solar power to microwaves either directly or indirectly, and an individual microwave radiator. Thus if any one of the subassemblies should fail there will be little reduction in the overall power transmitted.

The controller assembly may be preprogrammed to shape and direct the composite microwave beam by suitable phase control of the individual radiators or microwave transmitters, e.g. by a controlled phase shifting network connected to the various microwave transmitters, as is well known in the development of phased array radars.

Such a system may be based on earth or extraterrestrially, for example on the moon.

According to another aspect of the invention a lunar power system may be provided which comprises a solar power collection device, means for converting solar power into microwaves, and an array of separate microwave transmitters or radiators which when viewed from a receiver structure on earth will appear to fill an aperture of predetermined size such that the receiver structure is in the near field of the microwave beam. A suitable phase controlling system is provided to direct and shape the beam, and this can be controlled to take into account the variations in the relative positions of the radiating aperture on the moon and the receiver system on the earth during the monthly and annual cycles of the two planetary bodies. The phasing is suitably controlled via integrated circuits as is done in phased array radars. Thus the array of microwave radiators is beam shaped to illuminate a fixed Earth receiver or rectenna site as the lunar elevation changes. The beam is steered electronically via the phase control mechanism.

By positioning the microwave antenna structure on the moon, the effective aperture can be made very large, and much larger than any satellite-borne antenna. Thus the beam can be aimed more accurately, the rectenna can be located in the near field, and more power can be transmitted.

Thus it is an advantage of this aspect of the invention, that a lunar based power system can be provided that minimizes the need for Earth facilities to redistribute power and the quantity of power beams passing through the atmosphere of Earth, thus reducing environmental problems.

The system may also be used to supply reliable power to mobile airborne, or space orbital structures and systems on the moon to permit operation of a number of civil, industrial, scientific or military operations at locations desirable for mission requirements.

The lunar power system may also be used to provide local power in space and on the moon to permit expansion and further industrial development in the vicinity of the power plant so as to eventually provide construction materials and manufacturing capability for use in space or for return to Earth.

The lunar power system may use native, beneficiated and refined lunar materials, with a minimal deployment of earth-supplied materials, equipment, and manpower. Large amounts of electrical power may be recovered from relatively simple structures made primarily of lunar materials emplaced on and in the lunar surface, and such power could be used on the moon, beamed back to Earth directly or by use of orbiting structures to redirect the beams. As a result of the above, large amounts of power could be returned to Earth without requiring the lifting of large masses from either the earth or the moon and without the necessity of constructing large, highly integrated, multipurpose space vehicles or other complex orbiting structures.

The solar energy receiving or collection device is derived primarily from materials available on the lunar surface. This receiving device preferably comprises separate arrays of photoconverters positioned at locations generally corresponding to the earthward portions of the east and west limbs of the moon's diameter. However other locations ae possible. The solar power collection device in one embodiment is a plurality of ridges of photoconverters, each of the ridges having a glass-like surface covering compacted lunar soil. Each microwave transmitter is associated with a predetermined plot of ridges, and a plurality of segmented microwave transmitters and reflectors are coordinated across the array so as to be convergent on a given target associated with a receiver structure normally situated on Earth. The receiver structure has the capability of converting the microwave beam into electrical power suitable for use on electrical grids on earth.

In alternative embodiments, the present invention further comprises a lunar reflector maintained in orbit generally about the moon. This lunar reflector directs the solar radiant power to the solar power collection device on the lunar surface. The present invention may also further comprise a lunar orbital reflector or retransmitter device maintained in orbit about the lunar surface for directing the microwave beam from the radiating aperture on the moon to one or more receiver structures which may be on earth, in space, or on the moon at other locations. The present invention may further include one or more earth reflectors maintained in orbit about the earth for directing the microwave beam to the receiver structure. Each earth reflector will switch from one receiver structure to another during its orbit about the earth.

BRIEF DESCRIPTIONS OF THE DRAWINGS

The above and other objects and advantages of the present invention will become clear from the following detailed description of some preferred embodiments of the invention, taken in conjunction with the accompanying drawings, in which like reference numerals refer to like parts and in which:

FIGS. **1** A–E show the arrangement of lunar power stations on the moon and the sequential delivery of power to microwave receivers on Earth in a power transmission system according to one embodiment of the invention. The sequence illustrated by FIGS. **1** A–E illustrates the operation of the lunar power station as a function of the moon's rotation about the Earth. This view is in a reference frame fixed to the centers of the moon and Earth;

FIG. **2** is a schematic representation of a lunar power station according to one embodiment of the invention;

FIG. **3***a* is a schematic representation of the independent power collection and transmission plots which can be phased to form a lunar power station and to cooperatively beam power in a selected direction from the moon;

FIG. **3***b* is a side view of the arrangement of microwave reflectors with respect to central transmission device;

FIG. **3***c* is a front view as seen from earth of the arrangement of microwave reflectors about the lunar surface, illustrating the effective transmission aperture;

FIG. **3***d* is a side elevational view of a microwave reflector of FIG. **3***a;*

FIG. **4** is a graphical representation of the power generation capability of the lunar power stations as a function of the position of the moon in relation to the sun.

FIG. **5** is a cross-sectional view of the ridge form of the solar converter in accordance with one preferred embodiment of the present invention;

FIG. **6** is a cross-sectional view of an alternative embodiment of the solar converter of the present invention. Specifically, FIG. **6** shows a set of Chevron-like structures fused into the lunar soil;

FIG. **7** is a cross-sectional view of an alternative embodiment of the solar converter of the present invention, which is a high temperature cavity form of photoconverter;

FIG. **8** is a cross-sectional view of an alternative embodiment of the solar converter according to the present invention. Specifically, FIG. **8** shows a photoelectron emission device impressed into the lunar soil;

FIG. **9** is a perspective view illustrating an alternative embodiment of the ridge form of solar collectors and converters, in which a plurality of spaced and offset rows of ridge-form solar collectors are provided;

FIG. **10** is a top plan view illustrating the staggered arrangement of the ridges in FIG. **9**;

FIG. **11** is a side view of an alternative embodiment in which a series of smaller ridges of gradually increasing size or spacing are located on one or both sides of each converter mound or ridge;

FIG. **12** shows another modification in which reflecting structures are provided in grooves on one or both sides of each ridge.

FIG. **13** is a perspective view of another alternative embodiment of the solar converter of the present invention, in which the reflector is in the form of a parabolic trough with a series of convertor structures spaced along the base of the trough;

FIG. **14** illustrates the projection of incident and reflected solar rays on the converter of FIG. **11**;

FIG. **15** is an alternative embodiment of the lunar power station of the present invention in which a microwave reflector is positioned in earth orbit to direct the energy beam from the moon to a desired location on earth; and

FIG. **16** shows an alternative embodiment of the present invention in which reflector units are placed in orbit about the moon so as to redirect either radiant energy to the lunar surface or microwave beams from the lunar surface.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In all of the embodiments discussed below the provision of a power collection and transmission system on the moon for directing power to one or more receiver structures on the earth is described. However, it will be understood that the power transmission system may also be Earth-based, with suitable adjustments in the dimensions of the radiating aperture for transmitting power to an associated Earth-based receiver structure. In another alternative arrangement a lunar-based power transmission system may be associated with lunar, orbiting, or other non-Earth based receiver structures, either in addition to or in place of the Earth based receivers. The power transmission system need not be located on the moon but could be located on any suitable body in a sufficiently stable orbit about the Earth. Although the systems described below incorporate solar power collectors, other forms of power may be used for converting to microwave power, for example, fossil fuels.

The various embodiments of the invention illustrated in the drawings relate to the transmission of power in the form of a directed, convergent microwave beam **1** from one or more transmission systems **2** to the remote receiver devices **3**, the receiver devices being located in the near field of the microwave beam.

In the preferred embodiment of the invention one or more lunar power stations are provided for collecting solar power, converting it into an energy form suitable for transmission to earth, and transmitting the energy in a uniform and at least partially convergent beam directed at one or more receiver structures on Earth. The energy is preferably transmitted as a short, high frequency radio wave or microwave, but shorter wave visible, ultraviolet or infrared optical beams generated by coherent laser sources may alternatively be used.

FIGS. **1**A to **1**AE illustrate the positioning of two lunar power stations **16**, **18** on the moon **12** relative to receiver structures **20**, **22** and **24** on Earth during various phases of the moon. Each power station will comprise solar collector assemblies, converters for converting solar power to microwaves, and microwave transmitters or radiating antennas to transmit one or more microwave beams **26** towards the receiver structures on Earth. The converters may include devices for power accumulation, release and conditioning.

As shown in FIGS. **1**A to E, the solar power stations are located on the east and west limbs of the moon **12**, respectively. The receiver structures comprise microwave receiving units **20**, **22**, and **24** positioned about the surface of the earth. The microwave receiving units are positioned so as to receive the transmitted microwave beams from the transmitters on the moon. The operation of the lunar power system in relation to the relative motions between the moon **12** and the Earth **14** will now be described.

The operation of the lunar power station is sequentially illustrated by FIGS. **1** A–E. In these figures, a view of the moon **12** and the Earth **14** is shown from north of the ecliptic plane. The shaded areas are the night side of the two bodies. The moon is phase-locked with the Earth so that the same general side of the moon always faces the direction of the Earth. The moon rocks about the line between the centers by about plus or minus 7° or arc.

FIGS. 1A and 1E show the lunar power station system **10** of the present invention when the moon **12** is full as viewed from Earth. When the moon is full, the solar collecting assemblies in both power stations **16** and **18** collect solar radiant power since the sun acts on both units. The incident solar radiant power is converted to electrical power in D.C. or low frequency AC form. This photon to electricity conversion can be accomplished with direct photovoltaics, thermo-photovoltaics, heat engines, or other devices now known for such conversion. Some or all of the electrical power is reconverted and transmitted in the form of a coherent photon beam, such as microwave beam, to a single target on earth. This single target is microwave receiving unit **22** (FIG. 1A) located at a position on the moonward hemisphere of the earth. The microwave receiving unit **22** then converts the received microwave beam into energy usable in another form, such as electrical energy. As can be seen in FIG. 1A, the signals from the transmitters in power stations **16** and **18** are converged and directed toward the target area on Earth, as will be described in more detail below. While FIG. 1A shows the beams **26** as slightly divergent from the moon **12** to Earth **14**, it is preferable that beams **26** are convergent to a location on Earth **14**. The receiving area on Earth would not necessarily have to be larger than the transmission aperture on the moon. As illustrated in FIG. 1A, the amount of energy received and transmitted can be twice that available from a single unit of a given size located on the moon.

FIG. 1B shows the moon **12** in its last quarter. At this point in time, the solar collecting assemblies in power station **18** are in darkness while the power station **16** is exposed to solar radiant power. Since station **18** is not exposed to sunlight, no power is transmitted from unit **18** to Earth. However, each power station may be provided with suitable energy storage means, as described in more detail below, to permit transmission during periods of darkness. The transmitted microwave signal **26** shown in FIG. 1B is directed toward microwave receiving unit **22** on the Earth's surface during a portion of the time unit **22** is on the moonward side of the Earth.

FIG. 1C shows the lunar power station system **10** at new moon. No power is generated in this arrangement since both power stations **16** and **18** are in darkness. Hence, no power is transmitted in microwave form from the moon **12** to earth **14**. However, the power stations may include suitable energy storage devices to permit power to be stored during daylight periods for transmission during periods of darkness.

FIG. 1D shows the lunar power system **10** when the moon is in its first quarter. At this time, the power station **16** is in darkness and receiving unit **18** is exposed to sunlight. Receiving unit **18** transmits the solar energy in the form of a microwave signal **26** to microwave receiving unit **20** on Earth **14**.

Finally, FIG. 1E shows full moon **12**. As in FIG. 1A, both solar energy receiving units **16** and **18** focus and direct their microwave transmission **26** to receiving unit **20** on Earth. As shown in FIG. 1E, multiple beams **26*a*** and **26*b*** may be transmitted from a given unit such as **16** to two or more different receiving units, e.g. units **20** and **22**. As can be seen in a comparison of FIGS. 1A and 1E, the transmitter on the moon is synchronized so as to deliver power to the receiving units generally on the moonward side of the Earth. This will depend on the relative rotation of the Earth with respect to the moon. The receiving units on the far side of the Earth relative to the moon at any time may also be associated with suitable energy storage devices so that continuous power is available at any time. Many suitable storage methods are known, for example, pumped hydrostorage or compressed air stored in underground caverns.

FIG. 4 is a graphical representation of the power output curves for the lunar power station system **10**. In this graph, the total power generated by the lunar power station system is represented by the dotted line. The solid line represents the power that would be received by photoconverters of equal area placed flat on the lunar surface. This graph generally shows the power output as a function of the phase of the moon. As can be seen from FIG. 4, the maximum power is generated when the moon is full. This summing of transmitted power to high levels occurs in free space in the electromagnetic fields. The minimum power occurs near new moon. Between one or two days past new moon and just prior to full moon, the total power generated is relatively constant for a preferred collection geometry such as is shown in FIG. 5, for example (described in detail below). However, if continuous power generation is needed throughout the lunar cycle, one must either not transmit all the available power, storing the non-transmitted power for example by batteries, superconducting electrical coils and/or capacitors, flywheels, thermal or gravitational energy storage on the moon, or illuminate the solar collectors near new moon by using orbital sunlight reflectors or by relocating some of the collectors past the visible limb on the far side of the moon as viewed from Earth.

In the preferred embodiment of this invention, as illustrated in FIG. 1, the arrangement is to locate one transmitting array **18** on the east limb of the moon and another array **16** on the west limb of the moon. This will generally serve to provide a beam of power **26** toward Earth receivers **20**, **22** and **24** during most of the lunar month.

The specific form of each lunar power station **16**, **18** in the preferred embodiment of the invention will now be described. FIG. 2 is a schematic representation of one of the power stations during construction, and FIGS. 3*a* to 3*d* are schematic representations of solar power collectors and microwave transmitters in the power station. Each power station will comprise a plurality of separate solar collecting areas **50**, which need not be of equal size. Each collecting area is associated with a converter assembly for converting solar power into microwaves, and one or more microwave radiating or transmitting assemblies such as transmitters **54** and radiating antennas **59** for transmitting a microwave beam. Each transmitter **54** may comprise one or more individual microwave transmitters and may transmit a plurality of microwave beams. The transmitters may comprise microwave diodes, for example, which can be designed to transmit at least two simultaneous microwave beams. However, any suitable type of microwave transmitter may be used. In the preferred embodiment, the individual transmitters do not direct their transmitted beams in an earthward direction, but are associated with microwave reflectors or wavefront management devices **59** for directing the beams towards one or more receiver units on Earth. Each transmitter may be associated with one or more reflectors. The microwave transmitting system comprising the various microwave transmitters and associated reflectors is in form of an extended quasi-planar transmitting array. The relative phases of the transmitted microwave beams are controlled to form a composite microwave beam of predetermined shape and direction.

With the lunar power system shown, the receiver units can be located in the radiating near-field region of the transmitted composite microwave beam, and the various transmitted beams from the individual transmitters in the array can be controlled, for example by phase shifting integrated circuits as used in phased array radars, to shape and direct one or more composite microwave beams and to allow for the changes in the lunar elevation and the relative positions of the transmitter and receiver units as indicated in FIG. 1.

By positioning the transmitting system on the moon, there is little or no limitation on the overall size of the transmitting array. The radiating near and far field regions of a propagated wavefront are separated by the transition length, L, which is approximately given by:

$$L=D^2/w$$

in which D is the diameter of the radiating aperture and w is the wavelength. For microwaves, w is in the range from about 10^{-3} m. to about 1 m. For a wavelength of 10 cm. and a transmitting array diameter of 10 km, the transition distance to the far field is therefore 10^6 km. Thus, the Earth would be well within the near field of the transmitted composite microwave beam, allowing relatively precise directing and at least partial convergence of the beam onto a relatively small receiver unit. Because of the large lunar area availability, it would be feasible to construct much larger antenna arrays on the moon, for example of 100 km or more diameter, making the distance to the far field equal to 10^8 km. The Earth would then be even further within the near field, with consequent increased efficiency in power reception.

An oversized antenna aperture shared by many beams affords many methods for controlling multiple beams and the characteristics of any given beam such as diffraction limit, side lobe levels, position of beam center line, depth of field, and location of the focal region. The oversized array on the moon can use all the modern techniques of phased array electronics and geometric optics to control many separately directed beams simultaneously projected by each segmented array on the moon to form a shaped, convergent, composite beam. Thus, both small and large receivers on Earth or in space can be equally efficient in the reception of power. A 100 km diameter lunar antenna operating with 10 cm microwave would have a minimum central spot size at Earth of approximately 400 m. Most rectennas would be 2 or more times larger. A few hundreds of Megawatts of power could be received by a rectenna only a kilometer across.

FIG. 3 is a schematical representation of one embodiment of the lunar power station **16** or **18** incorporating an array of microwave transmitters located on the lunar surface. Generally, solar collector and converter devices or other energy sources are grouped into individual areas indicated by plots **50**. Electrically conducting wires **52** collect electrical power from the solar collectors and converters and conduct the electrical power to a central transmitter **54** associated with each plot **50**, which suitably comprises a plurality of microwave antennas. No particular wiring geometry is implied by wires **52**, as illustrated in FIG. 3. The general area **56** surrounding the array of microwave radiating assemblies, as shown in FIG. 3A, comprises a radiating or transmitting aperture. Either solid state or conventional means of generating coherent microwaves can be employed at transmitters **54**. Each transmitter **54** will normally comprise one or more individual microwave generators, such as microwave diodes, for example. Each plot **50** can be independent and separate from its neighbors for electrical collection. Electricity collection units and transmitters **54** in a given location may be interconnected by sub-surface wires **57** and switches. In this way, reliable transmission of power can be achieved even in the advent of a need to replace or repair solar collectors in a given plot **50**.

Each microwave transmitter **54** may be capable of producing more than one microwave signal. Transmitter **54** may contain microwave lenses and other devices for beam shaping. Multiple beams **26** may be generated by a given collection of radiating assemblies. These beams may be individually directed to different targets. The phasing of transmission is controlled by timing or reference signals from an external source so as to transmit a coherent composite microwave beam to microwave receiving units **20**, **22** and **24** located on earth **14**, or other locations in outer space.

In the preferred embodiment, an array of microwave transmitters **54** is provided which does not view the earthward direction of the transmitted beam. Instead, the energy from each microwave transmitter **54** is directed in a beam or beams **54***a* approximately in the opposite direction to one of a plurality of large microwave reflector surfaces **59** as shown in FIG. 3*b*. Each plot of collector assemblies **50** has one or more associated microwave reflectors **59**. Alternatively, the structures **59** may comprise microwave refractors and beams **54***b* may radiate through the refractors. Combinations of both techniques may be used.

The reflector is a structure substantially transparent to incident solar radiation, but which reflects microwaves. This arrangement permits the microwave radiating aperture to be interleaved with the solar power collectors while minimizing the blockage of sunlight to the collectors. FIGS. 3*b* and 3*c* illustrate this arrangement in relation to the lunar surface. The microwave reflectors **59**, when viewed from positions in the distance portions of the microwave beams will lie approximately within an area **56**. The reflectors **59** will cover enough of the area **56** when viewed from positions in a transmitted beam to define a transmitting aperture for the microwave beam. In FIG. 3*c*, the reflectors are shown as touching or slightly overlapping so that they fill the area or aperture **56** nearly completely. However, this is an exaggerated case and the reflectors need not overlap or touch as shown in FIG. 3*c*, but in fact the the total reflector size may be much less than the total area of the aperture **56**. The area **56** defined by microwave reflectors **59** has a generally circular shape as viewed in projection along beams **16** or **18**. This projected or multiple surface of microwave reflectors **59** produces a tighter and smoother beam than is possible with isolated small microwave transmitters.

Thus, a microwave transmission system is provided which comprises a plurality or array of separate microwave transmitters or radiators, whose virtual images approach or overlap when viewed from the microwave beam so as to present an apparently substantially contiguous radiating aperture **56** which may be 100 km or more in diameter. The aperture is preferably between about 100,000 and one million times the wavelength of the transmitted radiation diameter. Such a system may be used in other, Earth-based applications as well as in the lunar power system described with suitable reduction in the size of the array.

The use of a greatly expanded total lunar projected aperture and the operation in the geometrical optics—Fresnel diffraction region permits use of a truly convergent power beam with substantially uniform power flux density across the wave front which may be modified to allow differential convergence in transverse axes to shape the beam cross-section to match that of a fixed Earth receiver area. As the lunar elevation changes, the convergence may be accomplished by deactivating some of the array elements or transmitters **54** to change the active aperture perimeter **56**, by phase adjustment of radiating assemblies **54**, or by a combination of both these methods.

The polarization of the transmitted beam or beams may be controlled by one of two methods:

1. The polarization of the prime transmitting or radiating structures may be rotated by rotating said structures or by adjusting the phase and amplitude of 2 independent orthogonal sources.

2. The polarization may be changed from linear to circular or vice versa by using 2 orthogonal parallel wire reflecting layers spaced by about 1/8th wave length and fed by linear or circular polarized prime radiating structures respectively.

The Earth receiving units must effectively receive and rectify the transmitted beam over the range of azimuth, elevation and polarization planes characteristic of the process. The first two factors depend on time of transmission while the latter is adjustable by methods just described.

Each microwave radiator or transmitting assembly **54** in the preferred embodiment comprises one or more individual transmitters and a microwave reflecting surface or wavefront management device for reflecting microwaves from the or each transmitter to a remote receiver unit. Alternatively, an array of separate microwave transmitters may be provided which themselves direct the beam in the direction of a remote receiver unit.

FIG. **3*d*** shows an individual microwave reflector or wavefront management device **59**. Its appearance generally resembles that of a billboard. This microwave reflector **59** is constructed with foamed glass uprights **59*a*** and foamed glass horizontal members **59*b***. Uprights **59*a*** are anchored to the moon by pilings **59*c***. Crossed threads **59*d*** and **59*e***, formed of lunar glass or derived silicon, are extended taut across the frame so as to form a nearly flat or slightly curved surface. Threads **59*d*** and **59*e*** are coated with a thin film of electrical conducting metal, such as aluminum. This metal can be chemically refined from anorthositic lunar materials. The spacings between threads **59*d*** and **59*e*** must be significantly smaller than the wavelength of the photons used in the transmission system. The open space mesh reflectors will transmit at least 80 to 90 percent of the incident sunlight but reflect radiation of wavelength exceeding the average wire spacings by a factor of 5 or more.

It is possible to introduce more flexibility into power beaming by eliminating the fixed supports **59*c*** and by mounting the microwave reflector **59** on support **59*f***. Support **59*f*** is designed so as to rotate the reflectors **59** in azimuth and altitude. By phase controlling each of the individual microwave transmitters **54**, a wide range of beam transmission directions can be produced through the use of support **59*f***. The surface of the microwave reflector may be curved to aid in forming a beam.

The wavefront management devices **59** need not be reflectors as shown but may be of many different varieties. They may be lenses through which the microwave beam passes modified by controlled refraction. The wavefront management devices may be composed wholly or in part of active or passive phase delay elements. Hybrid systems with reflectors, lenses and active and passive multiple units may be used.

The wavefront management devices **59** may combine in their functions that of the transmitter **54**. Devices such as microstrip phased array transmitters can be made as large area devices which essentially fill the transmission aperture.

The wavefront management devices **59** in FIG. **3*c*** need not be placed in regular order but can be distributed pseudo-randomly so as to minimize power transmission in side lobes near the central beam direction. In addition, pseudo-random placements can permit transmitters which are less area-filling for given side lobes amplitude levels of the power beam.

The separate plots **50** of solar power collectors supplying power to the array of transmitters may be repeated over large areas of the lunar surface. They may be located across from each other on the lunar limbs or on the far side of the moon. They may be contiguous for the most part. In the preferred embodiment each plot is associated with a substantially central transmitting assembly **54**, but the transmitters may be positioned remote from the solar collector plots.

The radiating or transmitting assemblies **50** inside a given circle or radiating aperture, such as area **56** can be brought into phase so that the individual transmitters can act as a phased array which can generate one or more beams of power directed to one or more stations on Earth or to redirectors or reflectors in orbit about moon or Earth. Either signals from the earth or preprogrammed commands produced by phasing systems in space or on the moon can be used to define which ones of the plots **50** will perform as a coordinated array or aperture for a given time. Individual elements can be switched in and out during the operation of the array to change the shape or direction of the composite beam, for example, the center **58** of the transmitting array can be moved during transmission to change the path of the center of a given beam. The beam can be made convergent for a given target in the Earth-moon system because the effective aperture of the array is governed by the radius of the area **56** and can therefore be much larger than the aperture of the individual microwave transmitters **54**. The individual plots **50** do not have to be contiguous. However, as reflectors **59** fill up the projected area of the beam, then more photon energy is placed in the beam.

Each power station may include more than one transmitting array or aperture **56**. Different arrays can overlap so that the median of two areas **56** can contain plots **50** which may be side-by-side but are sending to different targets. The individual plots **50** do not have to be of the same size or the same power output. In addition, these plots **50** can be upgraded or repaired individually without having to shut down the entire system.

The array boundary **56** projected along the beam direction does not have to be circular, as in FIG. 3*c*, but can assume other shapes which are optimal for beam formation and focusing. More than one physically distinct array **56** can transmit to a target. The shapes of the individual plots **50** do not have to be square and the units do not have to be in contact. As an illustration of this concept, it is conceivable that an entire hemisphere of the moon could be used to produce a single beam if the individual units were present over a significant fraction of the lunar surface. The reflective surfaces or wavefront management devices **59** near the center of the lunar disk, as seen from earth, would be horizontal or almost horizontal to the local lunar surface. Transmitters **54** could be suspended above the reflectors **59** in towers.

The general physical orientation of transmitters and reflectors or wavefront management devices is somewhat dependent on their location on the moon and the direction of beaming from the moon. Horizontally oriented reflectors could be partially or fully covered by lunar soil to provide protection against temperature change, radiation and other disturbances. Temperature changes that occur on the lunar surface can induce physical dimensional changes and potential physical damage. Reflectors arranged generally parallel to and close to lunar slopes could also be partially or completely covered with lunar soil.

By operating with an at least partially convergent beam profile in the near field wave region, commonly described as the "Geometric optics—Fresnel diffraction" region, it is possible to control the cross-sectional area, shape and direction of the convergent microwave beam by altering the aperture perimeter by suitable switching of individual transmitters **54**, by adjusting the phases of transmission of the various transmitters, or by a combination of both of these methods. Thus, it is possible to ensure that the transmitted beam will fall on a fixed area of the Earth, or other remote receiver structure, in spite of the rotation of the Earth as viewed from the moon and orbiting of the moon relative to the Earth as long as the receiver site is on the moonward side of the Earth and not too close to the Earth's limb as seen from the moon.

As in standard phased array radar techniques, each element or radiator in the microwave array emits a quasi-spherical wave and the plurality of superimposed microwaves will combine constructively or destructively according to the phase differences. By suitable control of the signal phase the single composite microwave beam can be steered. Suitable phase shifters are used to shift the relative phases of the beam, and these may be microprocessor controlled.

The arrangement of two lunar power stations on the east and west limbs of the moon, as seen from the Earth, is used because of the fact that a given lunar station has useful illumination only when the sun's elevation is above some limiting lower value and hence less than 50% of the month or the year and similarly an Earth station could receive the transmitted power only when the lunar elevation exceeds some minimal value. So that continuous power can be delivered to a given Earth station, it thus becomes necessary to provide efficient, economical power storage or to add other operating elements to the system to extend operating time.

The cost of energy storage is composed of power dependent and energy dependent terms. Providing storage for the 15 days or more that a lunar base is in shadow or low elevation sunlight would be generally uneconomical. However, by using two lunar bases located close to the east and west equatorial limbs of the moon but displaced toward the sub-earth point sufficiently that lunar libration will not lower Earth's elevation angle below a minimum value needed to present needed aperture projected areas, the lunar bases could sequentially and cooperatively furnish power to one or more Earth receiving sites whenever the sites had sufficient lunar elevations, except for a short period near new moon. When both bases would be in shadow, the power interruption period would be total for about 1½ Earth days and the period of combined reduced and zero power would last up to about 3 days.

Provision may be made for energy storage at a single lunar power station for up to 3 Earth days' output or at both lunar stations for up to 1½ Earth days' output. This could provide for essentially continuous power beaming to a succession of Earth points following the Earth's rotation, except during lunar eclipse.

Energy may be stored either as thermal energy mechanical energy (e.g. kinetic energy of a flywheel or other structure), electrochemical energy (e.g. storage batteries, fuel cells), or gravitational potential energy, or electromagnetic energy (capacitors/inductors).

A possible gravitational potential energy storage method on the moon which would be equivalent to earth-based pumped hydrostorage methods would use lunar solids such as soil or rock. Two possible storage systems comprise mechanically transporting a mass of lunar soil from a lower to a high elevation during periods of solar illumination and recovering the energy by returning the mass to the lower elevation at night or low power periods. The transport mechanism may comprise a conveyor or pulley system, or a catapult method.

The period of zero or reduced power can also be lowered by siting the centers of solar power collecting plots **50** farther toward the lunar limbs than the centers of beam transmitting arrays at the expenses of increased lengths of power transmission lines (For every 370 km of combined displacement, the reduced power period is shortened by 24 hour). If the power conversion sites extend partially past the visible limb, it is possible to eliminate the periods of zero or reduced power.

Using either or both of the preceding methods to assure continuous lunar generation capability reduces the maximum duration of energy storage needed for a given Earth station to a fraction of a synodic day (24.84 hr) during which the lunar elevation is below a minimum useful value. For an equatorial Earth base, the storage duration may range from about 13 to 16 hours depending on cut-off angle, while for an Earth station at 45 degrees latitude, the average storage duration will be about 16.7 hr with an extreme value of about 19.3 hrs. Any conventional form of energy storage may be used. Alternatively, pumped hydrostorage, compressed air storage, or a combination of both, may be used. In one example, compressed air may be forced into a sealed reservoir which lifts the water to the surface. During energy recovery, the compressed air filled reservoir is expanded through a turbine to atmospheric pressure. The water is then allowed to flow to the lower reservoir through water turbines.

In addition to or instead of energy storage on Earth, orbital beam reflectors may be used to extend Earth base operation.

Some preferred forms of solar power collector and converter structures constructed in plots **50** to provide microwave power to the transmitter arrays will now be described. However, it will be understood that microwave power may be provided from other sources in alternative embodiments.

Collected solar power may be converted to microwaves either indirectly, by conversion of solar power to electricity and then from electricity into microwaves, or by conversion of thermal energy into electrical energy, or directly by conversion of sunlight into microwave photons for example by photoklystron devices.

FIG. **5** shows a first embodiment of an individual solar power collector and converter structure on the moon **12**. Specifically, this is a ridge-form of solar converter which can be formed on the moon **12** and used to receive solar radiant power from the sun. While this is the preferred embodiment of the conversion unit to be constructed on the moon, it should be noted that this is only one of a variety of possible devices for the conversion of sunlight to electricity or directly to microwaves (e.g. a photoklystron) which can be constructed on the moon primarily from lunar materials. A unique feature of the ridge-form of solar collector and converter structure **28** is that it uses the geometry of exposure to sunlight to even out the electric power production in the lunar day.

As can be seen in FIG. **5**, the lunar soil **30** is seived, smoothed, and formed into mounds **32**. A series of mounds **32** are aligned in the general north-south direction to cover the desired solar collecting area. These mounds **32** are nominally separated in the east-west direction by a distance sufficient to prevent excessive shadowing of each ridge by the next ridges in the lunar morning or evening.

The mounds or ridges need not be continuous but may comprise spaced rows of short ridges as shown in FIG. **9**. A thin layer **34** of native glass is applied to the ridge to bind together the sloping soil **32** as a cohesive layer. A thin layer **36** of iron or other electrically conductive, non-reactive (chemically) layer is vapor-deposited over the glass layer **34**. The iron layer **36** serves as the mechanical substrate and electrical pickup for a thin-film solid state photoconversion layer **38**. Photoconversion layer **38** is made of silicon. Other materials can also be utilized including those which could be imported from the Earth, (e.g. titanium, germanium, lower oxides of titanium, cadmium sulfide, lower sulfides of copper, selenides or tellurides of zinc, cadmium or copper, gallium arsenide, gallium phosphide, indium arsenide, manganese, iron, chromium, nickel or cobalt). A thin gridwork of iron **40** is vapor-deposited on top of the photoconversion layer **38** so as to complete the electrical circuit. A thin layer **39** of glass may be placed on top of photoconversion layer **38** so as to protect against solar wind, hydrogen atoms, and other forms of contamination. Electrical pickups are attached to the iron surfaces beneath the surface of the lunar soil **30** by leads **42** and **44**. Leads **42** and **44**, in turn, connect into the local power grid, as can be seen in FIG. **3**, for connection to associated microwave transmitting assembly **54**, which may comprise one or more microwave generators and antennas. The lunar iron in this solar converter structure **28** is acquired by beneficiating it in the form of micron-sized iron grains from the local soil, thermally separating it from adhering glass or minerals, and optionally electrorefining it on the moon. Silicon for use in the solar arrays can be obtained from the local lunar soil following the necessary chemical processing by means of machines brought from earth.

The ridges preferably take approximately the cross-sectional profile of an equilateral triangle. The spacing between the ridges is not critical. Such structures will effectively average the useful illumination and power collection over the period of lunar daylight.

The lunar environment is particularly suitable for the development of solar collectors and converters of this design. The lunar soils **30** are extremely good electrical and thermal insulators. There is no free oxygen or water in the lunar environment to damage, disturb, or interfere with the development and utilization of the solar converters. Finally, since the moon is seismically stable, the arrangement of ridges should remain free of significant geological disturbance.

The electrical output of a given inclined collector system can be augmented by diffusely reflected light. The contribution of diffusely reflected light will be greatest at local noon when the ground surface is at its brightest. The combined direct and diffuse illumination can be partially compensated by increasing the base angle of the ridge to greater than 60 degrees. The adjacent lunar soil surface reflectivity may also be increased by spreading a thin layer of white powder or glass material onto the surface, which can increase diffuse reflectivity to 90%. If this is applied for a distance of 3 face lengths in front of each ridge face and the base angle is also increased to 66 degrees, the noon illumination can be raised by about 24% and the average illumination may be raised by about 19% over solar elevations above 6 degrees.

FIG. **2** illustrates schematically an example of the construction of a lunar power station of the type shown in FIG. **3** made up of a series of areas or plots **50** of ridges as shown in FIG. **5** each associated with a microwave transmitter assembly and a reflector **59** of the billboard type. An automatic tractor **230** may be used to plow the lunar soil into a series of ridges. Power is brought by a grid of underground electrical wires from each ridge in a plot **50** to a collection of many solid state microwave transmission elements **54** at the center of each plot. The transmission elements **240** in a given plot illuminate the associated reflector **59** which is situated at the edge **232** of the plot or area remote from the Earth. The transmission elements in each plot are phased by local absolute clocks or a fiber optics network laid underground between the various transmitter sites in the array. FIG. **5** shows a ridge-form of solar collector and converter suitable for a lunar environment. However, there are other types of solar converters which would be suitable for the lunar environment. These types of solar converters could also make use of available lunar materials. As examples, alternative forms of solar collectors and converters are shown in FIGS. **6** and **7**.

FIG. **6** shows a chevron-like form **60** of solar collector and converter. Specifically, FIG. **6** shows a cross-sectional view of trenches created in the lunar soil by melting a small skin of lunar soil to form mechanically stable chevrons. The lunar soil **61** and the fused soil **62** form the body of this form of solar converter. The compacted lunar soil may have been stripped of various minerals and elemental components. The trenches **64** are of indeterminate length and can be adjusted to the most appropriate angle, size and length for the desired solar converter. A thin film of aluminum **66**, refined from lunar materials, is deposited on the spaceward facing surface so as to reflect direct sunlight **68** toward the back of the facing **70**. The back of facing **70** contains a photoconverter. Electrical attachments from the associated microwave transmitter to the photoconverter on facing **70** can be made through the soil **61** and the fused wall **62** by wires placed in the trench wall prior to the fusing of the soil. Connections between cells can be made by wires placed in the soil **61** under the converters and mirrors, thereby avoiding any contact with the plasma environment just above the lunar surface. Thin transparent cover sheets **71** can be placed over trenches **64** to provide additional isolation against contamination, solar wind, and cosmic rays. These transparent coversheets **71** are of the type which are less transparent in the infrared spectrum. These sheets **71** can also be used to smooth thermal changes at sunset.

In an alternative arrangement (not shown) the solar collectors and converters may be in the form of a series of V-shaped ridges and trenches. To produce power levelling in this type of structure, one side facing of each trench need not be flat but may be in the form of a series of short triangular ridges when viewed from above, similar to those shown in FIGS. **5** and **9** but rotated by nearly 90 degrees. The opposite side facing is a reflective surface forming a virtual image of the sun nearly in the horizontal plane, so triangular ridges with nearly vertical apex edges will experience nearly the same illumination sequence as the ridges of FIGS. **5** and **9**.

The trenches for the solar converters and mirror surfaces do not have to be open structures. An elaboration of the design is to make deep narrow cavities in which multiple light reflections are used to direct the solar energy to completely enclosed photoconverters. In this manner, a microenvironment can be created deeper in the lunar regolith to protect photoconverters from damaging photo and particle radiation, debris, sudden major temperature changes, etc. This shelter could be made predominantly from lunar material with simple thermal processing. The mirror surfaces do not have to be planar, but can be complicated shapes and even be optical gratings so that spectral splitting can be accomplished.

Mirrors **66** and optical cover **71** may be movable by means of thermally active hinges **100** or other solar tracking devices to allow one axis tracking of solar reflectors in orbit about the moon. They are preferably arranged to move so as to orient the surfaces as closely as possible to positions perpendicular to the incident solar rays throughout the lunar day.

Another form of the solar power collector and photoconverter structure is illustrated in cross-section at **72** in FIG. **7**. This structure **72** comprises a groove of any chosen length in the lunar surface connected to a high-temperature cavity **73** made of beneficiated native materials, such as anorthite or refined compounds or elements (e.g., Al_2, O_3 or Si). Cavities **73** can be buried under thermally insulating bulk or beneficiated lunar soils **74**. These cavities **73** can be partially filled with basaltic-like native or derived materials **74***a*. Materials **74***a* are of the type which melt at a significantly lower temperature than the materials forming cavities **73**. Solar energy **75** can be directed into these cavities **73** via simple reflectors **75***a* and **75***b*, either as concentrated sunlight (through windows **76** or other openings) or by electrical current through lines **77** and resistive heating element **77***a* during the times that regions **16** or **18** are illuminated. Since the axis of the moon is almost perpendicular to the ecliptic, relatively simple two-dimensional concentrators **75***a* and **75***b* with limited focus control **78** can achieve high concentration levels.

Power can be extracted from cavity **73** during the day and night by many means. Thermal energy could be extracted to provide process heat or drive turbines. High conversion efficiency output can be obtained by placing thermophotovoltaic solid state converters **79***a* in the cavity **73**. These thermophotovoltaics **79***a* are manufactured to convert photons, just off the peak energy density of the radiation in the cavity, into electricity. Non-converted photons are recycled and reequilibrated in cavity **73** for possible later conversion to electricity. Power is extracted through leads **79**. Cavity **73** can be thermally isolated at night by a cover sheet **76***a*. This cover sheet may be repositioned either automatically or mechanically by bimetallic devices over the entrance aperture. The cavity **73** may be permanently sealed by a glass lens or plate **76**.

This approach is practical on the moon because the lunar soil is an extremely good thermal insulator. Additionally, the lunar soil can be a source of supply for the components of the chamber and the molten material used for energy storage. Operating problems are reduced by the moisture and oxygen-free environment.

A similar approach may be used for thermal stage of power in systems of the type shown in FIGS. **5** and **6**. A large underground cavity of the type shown in FIG. **7** may be connected to the electrical grid of wires associated with one or more of the collector/converter arrays, and have a suitable heater for heating molten material in the cavity.

Another form of solar power collector and converter structure is illustrated in FIG. **8**. FIG. **8** shows in cross-section a structure which is suited for construction on the lunar surface from primarily native materials. A series of small, spaced trenches **80** are made in the lunar surface and a thin layer of photoemissive material **82** is vapor deposited over a thin film of aluminum **84** in the base of each trench. A thin film of aluminum **84** is connected by an electrical lead **86** to a larger grid of photoconverters. Sunlight **88** ejects photoelectrons **90** from the material. A small fraction of the photoelectrons **90** impact on either one of two anodes **92**. Anodes **92** are electrically separated by area **94** from the cathode **96**. Anodes **92** are made by vapor depositing a thin film of aluminum or other electrically conductive material on the slightly inward vertical walls **98** of trench **80**. The inward slope prevents direct illumination of the anodes **92** which suppresses back currents. The vertical walls are mechanically stabilized by fusing the soil **100** in a thin skin **102** after forming of the trench **80** in the soil **100**. The electron current flow is extracted by means of leads from the cathode **96** and the two anodes **92**. The leads **104** and **106** each introduce the power from this photoconverter section into the larger grid containing the array of microwave transmitters as in FIG. **3**.

In an alternative version of the photoconverter of FIG. **8**, the photoemissive layer **82** is vapor deposited on electrically separated small patches of electrical conductors in the bottom of the trench **80**. These conductors could be formed as small patches with smaller separating regions of non-photoemissive surfaces. The patches extend across the width of the trench. The width of each conductive line is approximately equal to the gyroradius of the photoelectrons (now perpendicular to path **90**) in the magnetic field of strip **107** which have energies of approximately 0.1 of the energy of the most populous of the differential photoelectron population of the emitted electrons. The electrons are made to have a gyroradius by layering native lunar irons in thin strips **107** under the patches or between the trenches **108** and **109** and magnetizing the iron layers so that a small magnetic field is impressed across the trenches parallel to the long axis of the photoconductive layers. Thus, most of the photoelectrons are made to step from one electrically conductive island to the next in the same direction down the long axis of the trench.

The cathode of the trench is the trench-end which the photoelectrons are moving away from, and will be the electrically positive lead end. The anode is at the other end of the trench. The device becomes more efficient as the separation distances between the edges of the islands decrease so that fewer electrons are impacted on non-conductive (electrically) soil. The efficacy of this approach is demonstrated by the fact that the magnetic fields on the lunar surface produce large potential differences by focusing the flow of solar wind electrons to the lunar surface and influencing the exact path of photoelectron return currents.

In another modification of the embodiment shown in FIG. **8**, multiple grids may be placed above the photoemissive layer **96** and biased electrically so as to force the photoelectrons to oscillate between the grids. This device is a so called photoklystron which permits the direct conversion of sunlight into microwave energy.

FIGS. **9** and **10** illustrate another alternative embodiment of the solar collector and converter structure. In this example, instead of spaced single continuous ridges, a series of rows of mounds or ridges **200** of the general type shown in FIG. **5** are provided. Each row is aligned in a generally north-south direction and separated from the next row in the east-west direction. As shown in FIG. **10**, the rows are staggered so that each mound in one row is aligned with the gaps between the mounds in the next adjacent row or rows. This can result in an equal or higher average illumination area for a given ground area.

The ground adjacent to ridges of the type shown in FIG. **5** or FIG. **9** may be provided with diffuse or specular reflection structures to increase average power collection and conversion. This is illustrated in FIGS. **11** and **12**. In FIG. **11** areas to the east and west of each mound of ridge **200** are provided with small ridges **202** of gradually increasing size. The ridges may be spaced so that a mid-point on the collector face **204** would see approximately equal fraction of the horizontal and inclined surfaces defined by the ridges **202**. White powder or glass material is applied over the surface of the ridge **area 206** so as to perform as an artificial "snow bank" or white sand surface. This raises the ground brightness and allows sunlight to be reflected from the ground area **206** onto the adjacent ridge or ridges. This arrangement may be arranged to produce an average ground brightness nearly independent of solar elevation.

Alternatively, as illustrated in FIG. 12, areas immediately east and west of the ridge faces **204** may comprise alternating specular and diffuse reflectors **208**, **210**. Specular reflectors **208** may comprise thin glass sheets or flakes with evaporated films of iron, nickel, aluminum, or other metals.

Alternate methods include many parallel layers of clear glass or molded prismatic glass sheets with V-shaped parallel grooves on the back side whose faces are inclined approximately + or −45 degrees to the planar front face. Horizontal specular reflectors can be conveniently prepared in-situ by applying radiant or other heat sources to smoothed lunar soil until it melts. Most lunar soils produce low viscosity glasses which level easily while the excellent thermal insulation qualities of the soil limit the depth of melt and serve as a container for the soil. After heat removal and solidification of the glassy melt, the surface may be metallized by vacuum evaporation of iron, aluminum, or other metal. The diffuse reflectors comprise layers of white powder to produce a snow bank effect.

Another example of suitable solar power collector and converter structure is shown in FIGS. **13** and **14**. In this example spaced split parabolic troughs **212** of specular reflectors lying along an east-west axis are prepared. The elevation of the bottom of the trough is conveniently set between about 30 degrees and 45 degrees while the elevation of the upper edge depends on the concentration ratio desired.

The projection of incident and reflected rays **215** on a north-south plane is independent of solar elevation and is shown in FIG. **14**. To achieve nearly uniform output power, solar converter structures such as photoconverters **214** comprising domed partial spherical structures or nearly equivalent polygonal solids are spaced along the base of each trough. The projected areas of the converters are nearly independent of direction. The east-west spacing of converter domes is established by minimum solar elevations for which no ray interferences is encountered, perhaps typical values of 3 to 10 converter diameters may be used.

Only a small fraction of the rays **215** striking the troughs reach the target converters at any one time. If power leveling is not needed or desired, one may use target converters of full length strips, cylindric or prismatic segments so that all rays which strike the trough will intercept the converters.

Solar radiation incident on the trough surfaces and reflected onto the converter surfaces will be suitably converted into electrical power for connection to microwave transmitters in the transmit array, as described above in connection with FIG. 3.

FIG. **15** illustrates an alternative system for transmitting microwaves from the moon to Earth. In this system, a microwave reflector or beam redirection device is provided in orbit about the Earth to direct microwave beams from the moon to receiving stations at high altitudes or angularly distant on Earth from the sub-lunar point. As shown in FIG. **15**, a power station **110** located on the earthward side the moon **12** beams a microwave (coherent photon) beam **112** toward the earth. The beam **12** is reflected onto a receiving station **114** on earth. At this receiving station **114**, the power in the photon beam **112** is converted into electrical current. On the opposite limb of the moon, a lunar power station **116** beams microwaves **118** to a microwave reflector or redirector device **120** in orbit **122** about the earth **14**. In this case the redirector device is a microwave reflector **120** which reflects beam **118**, as beam **124**, to a receiving station **126** on Earth. However, it may comprise any form of wavefront management device such as lenses, reflectors, active or passive phase delay devices, or reception and retransmission systems which re-transmit at the same or different frequencies to the input microwave beam. Device **120** may transmit more than one beam. It may transmit beams in directions corresponding to the angles implied by simple geometric reflection. It is important to note that as the number of receivers **126** and orbital microwave reflectors and re-directors **120** increase, more power can be transmitted to Earth.

The orbital device can be arranged to cooperate collectively with each other to direct power to all Earth stations at the level needed at a given time.

The rotation axis of the moon **12** is almost vertical to the ecliptic plane and makes an angle of approximately 1.5 degrees off the vertical. The rotation axis of the earth **14** is inclined approximately 23 degrees from the plane of the orbit of the earth about the sun. The direction of solar radiation is indicated by arrow **128** in FIG. **15**. The orbit **122** of the reflective mirror or re-director device **120** is established so as to most advantageously direct the microwave beam to the receiving station **126**, or to other users or devices in the vicinity of Earth. The orbit **122** is not necessarily a geosynchronous orbit or even in the plane or the equator of Earth. High inclination orbits can be established. The lunar power station **110** or **116** can supply power to the earth only when illuminated unless energy storage is provided. The earth is approximately fixed in the lunar sky of a given station. The lunar station is capable of directing the microwave beam to a given station on the earth as the station turns into view or directing the beam to reflectors in orbit about the earth **14**. Use of re-direction devices such as reflectors potentially enhances the ability to direct the microwave beam, to enhance the power transmission, and to deliver a more even flow of power to all stations on Earth from a minimum set of stations on the moon. The orbiting redirection devices or reflectors can become basic elements of a planet-wide power distribution system in which the power needed only enters the biosphere once.

Multiple re-direction devices or reflectors may also be used in orbit about the Earth. Power can be reflected or re-directed two or more times to reach users on Earth or in space. The reflectors **120** may also be configured as retransmitters. They could operate by receiving power at one frequency, converting it to another frequency, and then retransmitting it.

Another embodiment of the present invention incorporates the use of orbiting sunlight reflectors about the surface of the moon **12**. These orbiting reflectors can serve to increase the exposure of the lunar receiving units to sunlight and to increase the power transmission capabilities of the lunar power station. FIG. **16** is a view of the moon **12** from above the North Pole. The sunlight **130** is coming from the upper left and illuminating the moon hemisphere away from Earth. The dotted lines **132** and **134** define the extreme limits of the limb of the moon **12** as seen from the Earth. Lunar power station **136** is visible from the Earth at all times, whereas lunar power station **138** is invisible from the Earth at all times. The stations **136** and **138** are not necessarily on the equator of the moon and can be located nearer either pole than the equator and do not have to be distributed about the same latitudes. This figure reveals various ways that the power streams to the Earth can be smoothed in time.

The electrical energy at station **138**, as high voltage AC or DC, can be transmitted to station **136** by means of high voltage transmission line **140**. The power stream from the moon **12** to the Earth **14** will be smooth if two sets of these stations are located across the east and west limbs of the moon. At least one station of the four will always be illuminated and can send power to the corresponding earthward station for transmission.

The station **138** can direct a microwave beam to a microwave reflector mirror or other re-director device **144** in lunar orbit **146**. Microwave reflector **144** can then reflect the beam **142** into an earthward direction as beam **148**. Also, optically reflective mirror **150** in lunar orbit **146** (not necessarily the same orbit as for microwave mirror or re-director device **144**) can reflect sunlight **152** to the lunar surface as beam **154**. The sunlight is directed to the earth-side power station **156**, but may alternatively be directed to stations such as **138**. More than one mirror **150** can be used to illuminate a given lunar power station. From station **156** the microwave beam **158** is generated and directed toward Earth. Orbit **146** does not have to be circular or in the equatorial plane of the moon. Both types of redirector devices or mirrors **144** and **150** may be controlled by reaction engines, gravity gradients, tethers, moment of inertia changes or radiation pressure to point in the appropriate directions at the appropriate times to reflect beams. Device **144** and **150** could be the same type of re-director device, such as a mirror. Many mirrors and orbits can be used at the same time about the moon so as to minimize the need for multiple bases.

The variety or embodiments within the concepts as illustrated in FIG. **16** may be included to enhance the capabilities of this lunar power station in accordance with the present invention. The systems as shown in FIGS. **15** and **16** provide the capability to distribute power on a planet-wide scale so as to follow the diurnal patterns of power usage on Earth. Since the power only enters the biosphere once via the beams, the primary power production system can be minimized. As a result, this system provides for lowest costs and quickest completion. Intense power can be received almost anywhere on or above the earth via this system. It is not strongly dependent on local terrain, natural resources, or even the availability of land.

The use of a power station on the moon offers a number of advantages not found in prior actual or proposed extraterrestrial power systems. Of particular importance is the fact that the lunar power station could be constructed from materials found in abundance in the lunar soil. Even in the early stages of development, it would be possible to use substantial quantities of available lunar material for both the lunar power station and the production equipment used to build the station. One useful chemical element is iron, which can be separated by magnetic means from the bulk of the lunar soil with minimal complexity and minimal energy. This iron can be used for mechanical, electrical and magnetic functions. Other elements, such as the attached glass and assorted minerals may also be separated by several presently available techniques. The iron is present as tiny spheres and globes, many in the one to fifty micron diameter range, in both the soils of the lunar mare and highlands. Thermal heating can separate the iron from the glass using solar concentrators. It is advantageous in some applications to electrorefine the iron to remove minor amounts of nickel and cobalt. Because the lunar soil is pulverized, and due to the low lunar gravity, relatively little mechanical work is required to remove the iron metal from the local soil. The lunar soil and its derivatives may be used to provide structures, electrical and thermal insulations, transparent covers, and many other uses.

It should be noted that the various subsystems of a lunar power station as described above do not strongly interdigitate, as is the case with previously proposed satellite solar power stations (SPS). For example, SPS orbiting structures (microwave and/or optical collectors) must be optimized in mechanical properties to allow accurate pointing of portions toward earth targets and also to point another massive component toward the sun and, in addition, support interconnections between the power sources, the solar cells, and the mutually moving continuous antenna array. In the present invention, the solar conversion devices do not have to be optimized for minimal mass and maximum efficiency for use on the moon. In the present invention, these systems can be designed to be produced primarily out of the lunar feedstock with supplementation from minor-mass elements which may be needed from Earth. There is a minimal restriction to the use of solid state conversion devices for the lunar application. This lunar power station permits much more compact power receptors on earth than does the SPS system, may have improved reliability and is more immune than a satellite from meteoric of other space debris damage. It can also be readily modified and expanded with improving technology. Considerations of production and costs per watt become of direct relevance in the selection of the conversion device. Costs of transport from Earth and development of mass efficient devices (i.e. of low kg/kw) are of secondary concern since costs/lb are practically immaterial for mass sources already available at the point of use.

Advantages of solar based power stations as opposed to Earth based systems include reduced periods of low solar exposure during Earth winter. The synodic period for the moon is approximately 29.53 days. The lunar station is independent of cloudiness and is not exposed to such extreme weather conditions.

There are various other features of the lunar environment which are particularly conducive to the construction of lunar based solar power stations. These positive environmental factors include: (1) the very high vacuum and absence of disruptive chemical effects on thin-films; (2) the extremely stable mechanical environment of the lunar surface and its remoteness; (3) the complete dryness, high electrical resistivity and thermal insulating properties of the lunar soil which make it possible to build electronic components on and in the soil protect them from thermal changes, radiations, deliberate damage and plasmas; (4) vast areas are available for constructing large areas of converters and transmitters; (5) the moon is an exceptionally stable platform orbiting the Earth in a very regular and known manner; (6) chemically-free iron is available for the early stages of construction; (7) lunar derived materials can be used to support many phases of the space operations which support both construction of the lunar power system and other projects; and (8) simpler solar concentration systems due to the small lunar obliquity (1½ degrees). The Apollo, lunar science research, Skylab and shuttle programs have established the major portions of the research and development needs for the present invention. The tools necessary for high rates of production on the moon are within the state-of-the-art of present industrial capabilities.

Variations to this general approach are likely applicable to other natural objects in the solar system (e.g., Mercury, various asteroids, and the moons of Mars). Various non-microwave means of power transmissions are also clearly applicable (e.g., charged or neutral particle beams, lasers, etc.). On Earth, several different approaches to power reception are possible. These have been proposed for use in conjunction with the SPS. Such approaches to power reception could include heat engines driven by laser or particle beams. Photovoltaic arrays can be situated under the terrestrial rectenna elements of the microwave system.

For efficient power reception at the receiving units on Earth it is necessary that the amount of power reflected be minimized which requires that the gain and impedance of the receiving array antennas be properly matched to the input waves.

This can be done by individually rotating and aligning half wave or shorter dipole antennas of other directional antennas to proper directions to face the incoming power beams, but this is more costly than systems which use fixed structures.

For days in which the lunar maximum elevation is high and for non-equatorial Earth locations, it may be desirable and possible to collect power for lunar excursions of 120 degrees to as much as 180 degrees or more in celestial longitude (Right Ascension). Most fixed antenna systems cannot operate efficiently over a wide range of input angles. An exception exists for dipole or monopole antennas whose axes are perpendicular to the equatorial plane. These antennas have pattern symmetry about the polar axis but require input radiation polarized with electric vector parallel to the polar axis for maximum efficiency. This may be obtained by rotation of plane of transmission on the moon by +/−22 degrees to +/−25 degrees during a monthly cycle of operation. Actually the departure of a fixed direction of polarization (For example on the lunar or ecliptic pole) from ideal polarization is not serious and would result in a loss of about 7 to 9% of beam energy representing the orthogonal fraction.

A second alternative is to transmit a circular polarized wave which may be received using circular polarized omnidirectional antennas such as loop and monopole or slotted cylinder types with polar axes. For such systems, no adjustment of transmission polarization is required.

A further possible modification of receiver antenna systems is to use optical concentration by reflecting structures to raise the beam intensity and lower the actual active antenna aperture areas needed to process and rectify the power beam. While this would be a relatively simple matter for SPS Systems in which the beam direction does not change, it requires careful design for the lunar system with its variable beam direction. Most, if not all, high concentration ratio optical systems suffer severe spherical aberration errors if used over a large range of beam angles. One system previously described in the art which performs one axis concentration without measurable spherical or cylindrical aberrations is a circular cylinder with periodic reflector strips arranged along its inner surface. The angles between the strip change by only about one-fourth of the angular arc measured on the cylinder cross section. Input parallel rays are brought to a line focus on the projected extension of the cylinder, regardless of input direction. Use of such a concentrator requires either continual repositioning of the image receiver except when the moon is in the equatorial plane or else simultaneous rotation of the reflector strips. The reflector strips may be curved to correspond to surfaces on a torus to produce partial convergence and concentration along the other axis, but this will introduce some residual aberrations.

Beam concentration could result in radiation intensities which may be dangerous to bird and insect species in the receiver sites and require application of repellent techniques.

Beam reflector strips can be made of very low cost, open mesh reflectors.

The proposed lunar power system can use the moon, its environment, and its orientation in the earth-moon system as "gifts of nature", like coal or iron ore, to increase the net wealth of mankind with minimal destruction of natural resources.

The power transmitting system which permits transmission of power in a controllable microwave beam by means of an array of separate microwave transmitters is not limited in usefulness to a lunar environment but may also have applications to power transmission and receiving systems on Earth, in association with suitable power sources such as an assembly of solar power collectors.

A well defined microwave beam is possible because of the large transmitting aperture which may, for example, be synthesized from any appropriately positioned separate microwave transmitters, or combined transmitters and reflectors which completely or nearly completely fill the projected apparent aperture when viewed from a suitable receiver. Each reflector may serve as the reflection surface for hundreds, or even thousands, of individual microwave beams. When the segmented reflectors are used as part of a lunar power station, they are preferably arranged in an elliptical area near lunar limb so as to apparently overlap a filled, circular transmitting aperture 10 km to 100 km across when viewed from Earth.

To a first approximation, the segmented lunar antenna can be modeled as a set of spatially non-periodic radiators. The number (N) of radiators will be in the millions. The average intensity of stray power of a given beam will be 1/N of the intensity of the beam. It is conceivable that the stray microwave power of the LPS beaming 10,000 GWe could be less than a few billionths of a watt per square centimeter (few nanowatts/cm.**2) at Earth. This is a power level 10 to 100 times less intense than the human body radiates as incoherent power in the microwave region. If such a low level of incoherent stray power can be attained, then there is no biological risk from exposure to microwave outside the main beams. It may be possible to provide economic power via the lunar power system at beam intensities so low that heating of animals is negligible. Power would be cheaper at higher beam intensities.

Although some preferred embodiments of the invention have been described above by way of example, it will be understood by those skilled in the field that modifications may be made to the disclosed embodiments which are within the scope of the invention as defined by the appended claims.

We claim:

1. A solar power collection and transmission system comprising:

a plurality of solar power collecting assemblies for collecting solar radiation incident on said solar power collecting assemblies;

means defining a microwave radiating aperture of predetermined area comprising an array of separate, spaced apart microwave sources for emitting a plurality of separate microwave beams, and structurally separate microwave redirector means for redirecting the emitted microwave beams in a predetermined beam direction and expanding the effective microwave emitting area to substantially fill the microwave radiating aperture;

conversion means associated with each solar power collecting assembly for converting said collected solar power into a power form suitable for connection to said microwave sources;

each solar power collecting assembly and associated conversion means being connected to at least a respective one of said sources;

phase control means associated with said microwave sources for controlling the relative phase of microwave beams emitted from said sources to form a composite, shaped microwave beam directed from said microwave redirector means, the composite beam having separate radiating near field and far field regions; and

at least one microwave receiver assembly positioned in the radiating near field region of said microwave beam.

2. The system of claim 1, further including:

at least one receiver assembly remote from the radiating aperture and located in the near field of said composite beam;

said phase means further comprising means for directing said composite beam at said receiver assembly.

3. The system of claim 1, wherein said microwave redirector means comprise a plurality of microwave reflectors separate from said microwave sources for reflecting said microwave beams from said sources into said beam direction.

4. The system of claim 3, wherein said microwave reflectors are positioned so as to lie substantially within and cover substantially the whole area of the radiating aperture when viewed from a position in the composite microwave beam.

5. The system of claim 1 wherein each microwave source comprises at least one microwave generator and at least one associated radiating antenna, and said microwave redirecting means comprises a plurality of microwave reflective surfaces which are substantially transparent to incident sunlight and are positioned to reflect microwave beams emitted from said antennas in a predetermined direction, said microwave reflective surfaces being positioned to lie within said radiating aperture and cover substantially the whole area of said aperture when viewed from a position in said composite, shaped microwave beam.

6. The system of claim 1, wherein said solar power collecting assemblies each comprise an area of solar collector structures having photoconversion surfaces arranged to permit exposure to incident sunlight over a wide range of angles of incident sunlight and electrical connector means are provided for connecting said photoconversion surfaces in each area to a respective one of said microwave sources.

7. The system of claim 6 wherein each microwave source is positioned in a respective one of said solar collector areas.

8. A method of transmitting a microwave beam to at least one receiver located in the radiating near field region of the microwave beam, comprising:

collecting solar radiation incident on a plurality of solar power collecting assemblies;

forming a microwave radiating aperture of predetermined area by arranging an array of separate, spaced apart microwave sources to form a series of separate microwave beams directed at a series of separate microwave reflectors for reflecting and redirecting the separate beams into a common beam direction and expanding the effective microwave emitting area to substantially fill the microwave radiating aperture, the microwave reflectors being positioned so as to apparently define a radiating aperture of said predetermined area when viewed from the common beam direction;

connecting the microwave sources to conversion means associated with the solar power collecting assemblies for converting the collected power into a power form suitable for connection to said microwave sources, each solar power collecting assembly and associated conversion means being connected to at least a respective one of said microwave sources;

controlling the phase of the microwave beams emitted from the microwave sources so as to combine the separate beams into at least one composite, shaped microwave beam directed from said microwave reflectors, the composite beam having a separate radiating near field and far field region; and

receiving the microwave beam at at least one microwave receiver assembly located in the radiating near field region of the microwave beam.

9. The method of claim **8**, further including the step of:

positioning a microwave receiver structure in the near field of the shaped microwave beam.

[57] **ABSTRACT**

The implantable, electrically operated medical device system comprises an implanted radio frequency (RF) receiving unit (receiver) incorporating a back-up rechargeable power supply and an implanted, electrically operated device, and an external RF transmitting unit (transmitter). RF energy is transmitted by the transmitter and is coupled into the receiver which is used to power the implanted medical device and/or recharge the back-up power supply. The back-up power supply within the receiver has enough capacity to be able to, by itself, power the implanted device coupled to the receiver for at least 24 hours during continual delivery of medical therapy. The receiver is surgically implanted within the patient and the transmitter is worn externally by the patient. The transmitter can be powered by either a rechargeable or non-rechargeable battery. In a first mode of operation, the transmitter will supply power, via RF coupled energy, to operate the receiver and simultaneously recharge the back-up power supply. In a second mode of operation, the receiver can, automatically or upon external command from the transmitter, acquire its supply of power exclusively from the back-up power supply. Yet, in a third mode of operation, the receiver can, automatically or upon command from the transmitter, alternatively acquire its supply of power from either, RF energy coupled into the receiver or the internal back-up power supply.

RF COUPLED, IMPLANTABLE MEDICAL DEVICE WITH RECHARGEABLE BACK-UP POWER SOURCE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an implantable medical device including a rechargeable back-up power source and a charging unit for recharging the back-up power source via RF coupling.

2. Description of the Related Art Including Information Disclosed Under 37 CFR §§1.97–1.99

The concept of using an implantable, electrically operated medical device for treating specific diseases or physical disorders is well known. Examples of implantable, electrically operated medical devices are: cardiac pacemakers which restore a sick human heart to a normal rhythm, neural simulators which control nerve or brain response (such as pain or epileptic seizures), infusion pumps for subcutaneously drug delivery (such as insulin pump), and diagnostic devices for monitoring a patient's condition.

With respect to all of these implantable, electrically operated devices, it is necessary to provide power to the device implanted below the skin. Since the medical device is subcutaneously implanted in the patient, the power source must supply electrical energy for a reasonable period of time in order to reduce further surgical trauma to the patient and financial cost to the medical provider.

Implantable, electrically operated medical devices can be classified in three general areas: radio frequency (RF) coupled and partially powered implanted devices, non-rechargeable battery powered totally implanted devices, and devices which combine RF coupling and battery powered systems.

The RF coupled and powered devices do not carry or contain an independent power source. Therefore, the RF coupled device requires an external RF transmitter and a surgically implanted receiver. Such a device is an RF coupled neural stimulator. The RF link transfers stimulation pulses percutaneously through the skin and adjacent tissue layers of the patient from the external RF transmitter to the surgically implanted RF receiver and stimulator device. The transmitter sends, on a real-time basis, stimulation pulses to be applied ultimately to the implanted electrodes plus programming data defining the polarity of each electrode relative to each other to the implanted stimulation device. The implanted receiver obtains these stimulation pulses and programming data, converts pulses as necessary, delivers the energy contained in each transmitted stimulation pulse to the implanted electrodes as defined in the real-time programming data. The stimulation energy for each stimulation pulse is inductively coupled on a real-time basis from the external transmitter to the implanted receiver.

The common disadvantage of the RF coupled and powered stimulator is that the patient must always wear the external transmitter and antenna (even during sleep) in order for the implanted receiver to deliver stimulation pulses to the targeted tissue. Stimulation therapy ceases the moment the transmitter antenna is withdrawn just a few inches away from the implanted receiver. Although the RF coupled stimulator has this disadvantage, the service life of such an RF coupled and powered stimulator is not limited to the life of a battery contained within a fully implantable stimulation unit. Accordingly, the long term cost of the RF coupled and powered simulators is less than the non-rechargeable battery powered simulators because the service life of the former is much longer than that of the latter. RF coupled and powered simulators have been commercially marketed by Medtronic of Minneapolis, Avery Laboratories of New York and Neuromed of Dallas, Tex.

The battery powered stimulator utilizes a primary, non-rechargeable battery to power the implanted stimulator. The battery provides sole and exclusive power to the implanted stimulator continually while the stimulator generates one or more electric stimulation pulses, in a controlled manner, to the targeted tissue. Of course, the stimulation pulses are delivered to the targeted tissue via implanted leads. An external programmer may be used to non-invasively adjust the stimulation parameters, such as amplitude, pulse width or rate, or to control the duration of stimulation therapy each day. Programming may be provided through an RF telemetry link. After programming, the stimulator remembers the parameter values (the values are stored in an electronic memory) as long as the battery voltage remains above a minimum voltage level required by the electronics. Unfortunately, the service life of these battery powered implantable simulators is limited to the battery life. Accordingly, it is necessary to surgically remove and then replace the battery powered implantable simulators upon depletion of the electrochemically active materials in the battery. This disadvantage (i.e. surgical replacement) increases its long term cost to the medical provider relative to the aforementioned RF coupled and powered simulators. The battery powered implantable simulators do not require an external transmitter to deliver the stimulating electrical pulses. Accordingly, the battery powered implantable simulators are less complicated to use and more comfortable to wear than the RF coupled and powered simulators. Battery powered simulators have been marketed by Medtronic of Minneapolis and Exonix of Miami.

A third category of implantable, electrically operated devices include neural simulators which combine the RF coupled/powered systems with the battery powered implantable stimulator technology. These types of simulators enable the patient to obtain therapy without the necessity of having an external RF coupled unit proximate to the implant at all times. However, the stimulator must be surgically replaced after the battery is depleted if use of the external RF transmitter is not desired. This type of stimulator allows RF coupled stimulation at times when wearing the external transmitter is not objectionable, thereby extending battery life. Also, this type of stimulator may allow for continuing RF coupled stimulation after the internal power source is depleted, although some of these RF coupled and battery powered implantable simulators do not operate if the battery is completely depleted in the implanted stimulator.

Several examples of such previously proposed implantable devices are disclosed in the following U.S. patents:

U.S. Pat. No.	Patentee
4,408,607	Maurer
4,793,353	Borkan
5,279,292	Baumann et al.
5,314,453	Jeutter

U.S. Pat. No. 5,314,453 to Jeutter describes and claims an implant "locator" means to aid in locating an implanted device. The locator means comprises a reed switch affixed to the center of a transmitting coil and a magnet affixed within the implanted device. Transmission of high frequency RF energy is possible only when the reed switch is closed by the magnet within the implanted device, thus insuring some degree of good coupling between the transmitter and receiver. However, this patent describes a full wave rectifier along with rechargeable batteries. Accordingly, it incorporates a rechargeable battery. The present invention differs from the teachings of the Jeutter patent in the following respects:

1) Charging current is controlled by battery temperature to prevent gas generation by the battery and loss of battery electrolyte,
2) A real-time feedback system is provided between the receiver and the transmitter for real-time adjustment of the RF energy generated by the transmitter, thereby extending the service time of the transmitter's battery.
3) A low frequency RF coupling method (10 to 500,000 Hertz) is provided which allows RF coupling through a titanium encased receiver. The RF coupling system described by Jeutter operates at a very high frequency of 2,000,000 Hertz which is greatly attenuated by any metal enclosure. Jeutter describe an epoxy potted receiver which differs from a titanium encased receiver housing.
4) The receiver is capable of automatic switching the supply of power between RF coupled power upon sensing RF energy or battery power upon sensing loss of RF coupled power.

U.S. Pat. No. 5,279,292 to Joachim Baumann et al. teaches a series resonant circuit in an implantable device. The device disclosed hereinafter uses a parallel resonant circuit which can be tuned at low frequencies, 60 Hz to 500 kHz, such as, for example 8 kHz, which couples well through a titanium enclosure. Further this patent does not teach adjusting charging current as a function of battery temperature or controlling the charging current with the current output from a D/A converter.

U.S. Pat. No. 4,793,353 to William Borkan discloses a non-invasive multiprogramable tissue stimulator which utilizes RF coupling to charge and recharge a capacitor or other rechargeable voltage source. The Borkan circuit differs from the circuit disclosed hereinafter in several respects:

1) First of al in the Borkan circuit, while in the RF stimulation mode, each stimulation pulse must be generated and transmitted by the transmitter, on a real time basis, to the implanted receiver (in contrast, the receiver disclosed hereinafter incorporates all the elements required to autonomously generate and regulate the stimulation pulses);
2) Borkan teaches that a non-rechargeable battery can be used as an alternative power source to RF coupled stimulation, while the circuit disclosed hereinafter uses a rechargeable battery which can be "fast" or "trickle" recharged via low to medium frequency (10 to 500,000 Hertz) RF coupling while Borkan uses a much higher RF coupling (2,000,000 Hertz).

U.S. Pat. No. 4,408,607 to Donald Maurer teaches a capacitive energy source and associated circuitry for powering a medical apparatus. The Maurer circuitry differs from our the circuitry disclosed hereinafter in that:

1) The Maurer battery is non-rechargeable and only is used to power the implanted receiver during charging of the capacitor (the main power source);
2) Maurer provides no means for non-invasively recharging the battery;
3) Maurer does not control the charging current to a battery relative to the temperature of the battery to prevent gas generation by the battery and loss of battery electrolyte.

Moreover, Maurer does not teach the capability to switch automatically between RF coupled (power upon detection of RF energy) and battery power (upon sensing absence of RF energy).

SUMMARY OF THE INVENTION

According to the present invention there is provided an implantable, electrically operated medical device comprising an implanted radio frequency (RF) receiver incorporating a rechargeable back-up power source and an external RF transmitter. RF transmissions are coupled into the implanted receiver for powering delivery of medical therapy and simultaneous recharging of the back-up power source within the receiver. The back-up power source has enough capacity to be able to autonomously power the receiver for at least seven days during continual delivery of medical therapy. The receiver is surgically implanted within the patient and the transmitter is worn externally by the patient. The transmitter can be powered by either a rechargeable or non-rechargeable battery.

In a first mode of operation, the supply of power to operate the receiver, recharge the back-up power source and deliver therapy is acquired primarily from the RF energy coupled into the receiver, until the receiver senses a loss of RF power at which point it will automatically switch to the back-up power source in order to continue delivery of medical therapy. In this first mode of operation, the transmitter will transmit lower energy RF waves since the back-up power source is recharged at a slower rate.

In a second mode of operation, the receiver can, automatically or upon external command from the transmitter, acquire its supply of power exclusively from the back-up power source. In the second mode of operation, the transmitter will transmit high energy RF waves in order to recharge the back-up power source at a faster rate and will terminate the RF transmission upon receiving from the receiver a "termination command" which indicates that the back-up power source is fully charged.

Yet, in a third mode of operation, the receiver can, automatically or upon command from the transmitter, alternatively acquire its supply of power from either or both, RF energy coupled into the receiver and/or the internal back-up power source. This third mode of operation is useful in patients where it is desirable to power the receiver from RF coupled energy during periods of awakeness, but switch to the back-up power source during sleep for greater comfort. In this third mode of operation, a real time clock within the receiver can be programmed by the transmitter with different start/stop times for RF coupled power than for back-up battery power. In this fashion, the switching is done automatically and the external transmitter unit will alert the patient which is the source of power for the receiver at all times.

The receiver includes a mechanism for alerting the patient when the back-up power source is nearing depletion and needs to be recharged. The mechanism can include: 1) a vibrating device within the receiver; 2) an audible tone generating device within the receiver; or, 3) a specific message shown in the transmitter's display combined with a specific audible tone generated by the transmitter.

The transmitter incorporates a transmitting antenna which generates RF wave-fronts which are coupled into an inductor within the implanted receiver. This RF coupled power, which is alternating current or AC in nature, is rectified, filtered and converted into a high DC voltage within the receiver. Further, a voltage regulator within the receiver converts the high DC voltage into a lower precise DC voltage from which the receiver operates.

It is the objective of the present invention to provide an implantable, electrically operated medical device (receiver) capable of obtaining its source of electrical power from either, an external battery coupled via low level RF transmissions (transmitter), or a back-up rechargeable battery contained within the implanted receiver.

According to one aspect of the present invention, there is provided a method of supplying power, on an exclusive basis, from externally low energy RF coupled power (transmitter), to an implanted receiver during continual delivery of medical therapy.

According to another aspect of the present invention, there is provided circuitry for programming into the receiver the times of day (meaning a continuous 24 hour period) in which the receiver automatically switches it's supply of power from RF coupled energy to the back-up power source, and vice-versa.

According to still another aspect of the present invention, there is provided a method for recording into a non-volatile memory contained within the implanted receiver the stimulation values and other critical data, so that it will not be erased if the back-up power source is depleted and to eliminate the need for the transmitter to generate and regulate, on a real time basis, the delivery of medical therapy.

According to still another aspect of the present invention, there is provided a method of supplying power, on an exclusive basis, during at least a seven day cycle of substantially continual delivery of medical therapy utilizing a rechargeable power source.

According to still another aspect of the present invention, there is provided a method for non-invasively recharging the power source within the receiver, whereby the electrical energy contained in the battery powering the external transmitter is transferred into the rechargeable power source within the receiver utilizing an inductive RF power link between the external transmitter (recharging unit) and the implanted receiver (unit being recharged).

According to still another aspect of the present invention, there is provided a method for regulating the rate of recharging the back-up power source contained within the implanted receiver as a function of temperature of the back-up power source, in order to inhibit the power source from generating harmful gases and to prevent electrolyte loss, thereby enhancing the service life of the back-up power source and increasing the possible number of recharge cycles.

According to still another aspect of the present invention, there is provided a method, interactive between the transmitter and receiver, for regulating the RF energy generated by the external RF transmitter as a function of distance between the transmitting and receiving inductors.

With these methods, the level of RF energy coupled into the receiver antenna is monitored by the receiver which telemeters specific commands to the RF transmitter to adjust the RF energy level being generated. This real-time feedback system allows generation of just the minimum RF power needed at the receiver, thereby extending the service time of the battery powering the RF transmitter.

According to still another aspect of the present invention, there is provided in transmitter for the patient to select between RF powered operation only, back-up power source operation only, or a combination of both. If "RF power" is selected, the implanted receiver will only operate when the transmitter unit is proximate to the implanted receiver, and the transmitter will generate low level RF energy. If "back-up power" is selected, the implanted receiver will draw it's operating power exclusively from the back-up power source, and the transmitter will generate higher level RF energy when used to quickly recharge the back-up power source. If "combination power" is selected, the implanted receiver will draw it's operating power from the transmitter via low level RF coupled energy, but will automatically switch to draw it's operating power from the internal back-up power source when the transmitter is removed or turned off. The patient may select one of these options via a specific menu shown in the transmitter's display.

According to still another aspect of the present invention, there is provided a method for the receiver to automatically terminate the recharge cycle upon sensing a fully charged back-up battery by the transmission of a specific telemetry command to the transmitter, thereby enhancing the service life of the battery powering the RF transmitter.

According to still another aspect of the present invention, there is provided several receiver-initiated commands for alerting the patient when the rechargeable power source is nearing depletion and needs to be recharged. Some alerting signals are generated by the receiver itself and other alerting signals are generated by the transmitter.

According to still another aspect of the present invention, power sources and methods are utilized for non-invasively coupling energy and recharging the implanted battery, in combination with an implantable tissue stimulator.

According to still another aspect of the present invention, there is provided an implantable drug delivery system utilizing these power sources and methods for non-invasively coupling electric energy into the implanted drug delivery system and recharging its battery.

According to still another aspect of the present invention, there is provided an implantable monitor and diagnostic system utilizing these power sources and methods for non-invasively coupling electrical energy into the implanted monitor which is used to collect vital physical data from the patient which can be interrogated by a receiver external to the patient.

According to still another aspect of the present invention, there is provided an implantable cardiac pacemaker utilizing these power sources and methods for non-invasively coupling electrical energy into the implanted pacemaker and recharging its battery.

According to still another aspect of the present invention, there is provided an implantable cardioverter/defibrillator utilizing these power sources and methods for non-invasively coupling electrical energy into the implanted cardioverter/defibrillator and recharging its battery.

According to still another aspect of the present invention, there is provided a method for recharging power via an inductive RF power link between the recharging unit and the implant and through the hermetic titanium encasement of the implant.

According to still another aspect of the present invention, a patient is permitted to vary the delivery schedule and/or quantities of the medical therapy via the external RF transmitter/recharger unit.

According to still another aspect of the present invention, a medical physician, nurse or technician is allowed to program into the implanted medical device, via the external RF transmitter/recharger unit, the delivery schedule, values or quantities of the medical therapy and to set the limit for these schedules, values or quantities within which the patient may safely adjust them later on.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a block electrical, schematic circuit diagram of the overall system including a transmitting unit and an implanted receiver unit configured for an implantable, rechargeable tissue stimulator system.

FIG. **2A** is a block electrical schematic circuit of a digital to analog converter in the receiver unit

FIG. **2B** is a detailed electrical schematic circuit diagram of the digital to analog converter with current output shown in FIG. **2A** which is used, under control of a micro controller, to regulate the constant current rate for recharging the back-up power source within the implanted receiver unit.

FIG. **3** is a block electrical schematic circuit diagram of the overall system as configured for an implantable, rechargeable drug delivery system.

FIG. **4** is a block electrical schematic circuit diagram of the overall system as configured for an implantable, rechargeable cardiac pacemaker system.

FIG. **5** is a block electrical schematic circuit diagram of the overall system as configured for an implantable, rechargeable cardioverter/defibrillator.

FIG. **6** is a block electrical schematic circuit diagram of the overall system as configured for an implantable, rechargeable monitor and diagnostic system.

DESCRIPTION OF THE PREFERRED EMBODIMENT(S)

Referring to the drawings in greater detail, there is illustrated in FIG. **1** a block electrical schematic circuit diagram of an implantable, rechargeable tissue stimulator system **10**. The system **10** includes a transmitter **12** and a receiver **14**, the latter being surgically implanted beneath a patient's skin **16**. The receiver **14** is connected, via lead connector **18**, to an implanted medical device, which in this embodiment, is an implanted lead **19** which contains, at it's distal end **20**, stimulating electrodes **21–24**. These electrodes **21–24** are implanted adjacent to the target tissue to be stimulated (i.e., a specific nerve or a nerve bundle, a specific area of the brain or a specific muscle within the human body). The implanted receiver **14** receives therapy values, transmitted by the transmitter **12** via RF signals, which are decoded by decoder **25** and then stored in a non-volatile memory (EPROM) **27**.

Referring again to FIG. **1**, the major components of the transmitter **12** are a micro controller **26** which is used, via software, to: 1) control the output of a programmable DC to DC converter **28** in order to regulate the amount of RF energy to be coupled into the receiver **14**; 2) read data and command inputs inputted via a keyboard **30**, display messages and menus via a display **32**, transmit therapy parameter values, via a programming encoder **34**, a transmit driver **36** and an antenna **38**, to the implanted receiver **14**; 3) and receive commands and patient's diagnostic data, transmitted from the implanted receiver **14**, via the antenna **38**, an amplifier **39** and a decoder **40**.

As shown in FIG. **1**, when the transmitter **12** is powered up via a switch **41** and a "start therapy" key **42** on the keyboard **30** is pressed, the transmitter **12** will transmit the "start" command to the receiver **14** which will initiate delivery of therapy by the receiver **14**. Likewise, if a "stop therapy" key **43** on the keyboard **30** is pressed, the transmitter **12** will transmit the "stop" command to the receiver **14** which will cease delivery of therapy.

The implanted receiver **14** of FIG. **1** can be programmed by the physician or patient to obtain it's operating power from one of three sources: 1) RF coupled energy only; 2) back-up rechargeable power supply/source **44** only; or 3) a combination of both whereby the implanted receiver **14** alternates automatically from one to the other according to a preset schedule programmed via the transmitter **12**.

When "RF only" is selected from a menu displayed by the display **32** of the transmitter **12**, an output port **45** of a micro controller **46** in the receiver **14** is switched to a "0" and a port **47** is switched to a "1" which places pmos transistor P2 in a conducting state and pmos transistor P1 in a non-conducting state. This effectively connects a line conductor **50** to a line conductor **52**, making VDD equal to the output of a voltage regulator **54** which is at +3.0 vdc.

When "battery only" is selected from the same menu, the output port **47** is switched to a "0" and the port **45** is switched to a "1", thus effectively connecting line conductor **56** to line conductor **52** and making VDD equal to the voltage level at the rechargeable power source **44**.

As shown in FIG. **1**, when "combination" is selected from the same menu, the system **10** will automatically switch the source of VDD to the output of the voltage regulator **54** (line conductor **50**) when the transmitter **12** is proximal to the receiver **14**, or to the rechargeable power source **44** when the transmitter **12** is removed away from the receiver **14**. The automatic switching is performed by the micro controller **46** in response to the state of line conductor **50** which is at +3.0 volts when RF energy is being coupled into an inductor **60** (the transmitter **12** is proximal to the receiver **14**) or is 0 volts in the absence of RF energy (the transmitter **12** is away from the receiver **14**).

When the receiver **14** is programmed to "battery only" power acquisition mode, it's exclusive source of operating power becomes the rechargeable power source **44**. After prolonged use, the rechargeable power source **44** will reach a near depleted level, at which point the receiver **14** will transmit, via an RF communication link **61**, a "recharge" command to the transmitter **12**. This will cause the transmitter **12** to generate, via the battery **62**, the DC/DC converter **28** and an output inductor **64**, high energy RF waves which are coupled into the inductor **60** contained within the receiver **14**. The actual level of RF energy generated by the inductor **64** is regulated by an output port **70** of the micro controller **26** as a real-time response to data transmitted by the receiver **14** via the micro controller **46**, the data representing the voltage level E1 at the output of the rectifier **74** in the receiver **14** which is measured via an attenuator **76** and an analog to digital converter **78**. This feedback system extends the life of the battery **62** within the transmitter **12**, by adjusting, as a function of distance between the inductors **64** and **60**, the RF energy required to quickly recharge the rechargeable power source **44**. A close proximity requires much less RF energy to recharge the rechargeable power source **44** than a longer distance would, in the same time. During this recharging operation, the micro controller regulates, as a function of temperature, the current level used to recharge the rechargeable power source **44**. The temperature is measured by a thermistor **80** which is adhered to the rechargeable power source **44** during manufacturing. The junction between the thermistor **80** and a resistor **82** form a voltage divider which is fed through an analog switch **84** to an analog to digital converter **86** and, via a line conductor **88**, to the micro controller **46**. As the voltage rises, the ohmic value of the thermistor **80** drops proportionally to the temperature, thus reducing the voltage at the line conductor **88** to the micro controller **46**. This loop forms a temperature-controlled, current-regulated charging system which restricts the temperature rise of the rechargeable power source **44** during recharging, thus preventing the power source **44** from suffering electrolyte starvation and gas generation. Both of these phenomena will, if left unchecked, dramatically reduce the reliability and service life of the power source **44**. Also, during recharging of the power source **44**, the micro controller **46** will monitor the voltage level of the power source **44** via a line conductor **90**, analog switch **92**, the A/D converter **86** and, finally, the line conductor **88**. Upon sensing a fully charged state, the micro controller **46** will telemeter to transmitter **12**, via the RF communications link **61**, a "stop" recharging command and simultaneously will turn off a D/A converter **94** which will cut off the current needed to charge the rechargeable power source **44**. In this manner, the power source **44** cannot be overcharged, even if the "stop" command was not received by the transmitter **12** due to electromagnetic interference.

Referring to FIG. **1**, when the receiver **14** is programmed to "RF only", the power acquisition mode, it's exclusive source of operating power is the low level RF energy generated by transmitter **12** and coupled into the inductor **60** within the receiver **14**. The actual level of RF energy generated by the inductor **64** is regulated by the output port **70** of the micro controller **26** to the minimum level required to operate the receiver **14** and the rechargeable power source **44** is trickle charged, as a real-time response to data transmitted by the receiver **14** via the micro controller **26**, i.e., the data representing the voltage level E1 at the output of the rectifier **74** which is measured via the attenuator **76** and the analog to digital converter **78**. This feedback system extends the life of the battery **62** within the transmitter **12**, by adjusting the RF energy required to operate the receiver **14** and maintain a trickle charge to the rechargeable power source **44**, as a function of the distance between the inductors **64** and **60**. At close proximity, much less RF energy is required to accomplish these functions than at a longer distance.

During trickle charging, the micro controller **46** regulates, as a function of temperature, the current level used to trickle charge the power source **46**, by the same method already explained in the previous paragraph. Again, this prevents electrolyte starvation and gas generation within the rechargeable power source **44**. Also, during trickle charging, the micro controller **46** will monitor the charge level of the power source **44**, and upon sensing a fully charged state, the receiver **14** will telemeter to the transmitter **12** the "stop" recharging command and simultaneously will turn off the D/A converter **94** which will cut off the current needed to charge the power source **44**. In this manner, the power source **44** cannot be overcharged, even if the "stop" command was not received by the transmitter **12** due to electromagnetic interference.

When the receiver **14** is programmed to "combination" power acquisition mode, the micro controller **46** will automatically switch delivery of operating power to the receiver **14** to RF coupled energy upon detection of RF induced voltage at E1. Likewise, the micro controller **46** will switch delivery of operating power to the rechargeable power source **44** upon loss of RF induced voltage at E1. The patient may select, via a menu shown in the transmitter's display **32**, fast or trickle charge to the rechargeable power source

Upon sensing that the charge in the rechargeable power source **44** is below a predetermined level, the micro controller **46** signals the patient, via an audible alarm **96** and/or a vibrating alarm **98**, that the rechargeable power source should be recharged.

Referring to FIG. **2B**, a detailed electrical schematic of the digital to analog (D/A) converter **94** is provided. The D/A converter **94** is software programmable, precision current source whose output is regulated by the micro controller **46**. It should be noted that this type of D/A converter is best implemented into an integrated circuit where the electrical characteristics of the transistors can be precisely matched.

Referring again to FIG. **2B**, resistor **R1** is used to set the base bias current for the converter **94**. Transistors **N17** and **N1** form a 1:1 current mirror where the current into the transistor **N17** equals the current through the transistor **N1**, since both transistors have equal channel width and length. However, the channel width for the transistors **N2** through **N8** are binary weighted, so that the transistor **N2** has twice the width of the transistors **N1**, **N3** has twice the width of **N2**, and so forth. This binary scaling results in transistor **N2** conducting twice the current of transistor **N1** (assuming equal bias current), the transistor **N3** conducting twice the current of the transistor **N2**, and so forth. The transistors **N9** through **N16** are used as pass devices to allow the current available at the transistor **N1** through the transistor **N8** to pass to the current sum line **1**. The on-off state for the transistors **N9** through **N16** is governed by inputs **i1** through **i8** which, in one embodiment, are output ports from the micro controller **46** (bus line **100** in FIG. **1**). In this manner, the micro controller **46** is able to select any value of current between 1 and 256 times that of the current flowing through the resistor **R1** (bias current) to pass to the current sum line **1**.

Input line "enable.n" is used to turn on and off the D/A converter. When "enable.n" is a "0", the transistor **P1** conducts connecting VDD to the sources of the transistors **P2** and **P3** which form a 1:1 current mirror. Therefore, the current sourced by the transistor **P3** equals the current flowing through the transistors **P2**, **P3** being the output current device ("iSOURCE") for this D/A converter **94**.

In FIG. **3** is shown a block diagram for an implantable, rechargeable drug delivery system. The block diagram for the transmitter **12** is the same as for the transmitter **12** shown in FIG. **1**.

The block diagram for the receiver **14** contains the same power supply system, supply switching means and method for recharging the rechargeable power source **44** that has been already described above in connection with the description of FIG. **1**, but has been modified to incorporate the components required to assemble an implantable drug delivery system. These components are: 1) a drug reservoir **104** which contains the drug to be delivered by the receiver **14**; 2) a refill septum **106** used to percutaneously, via a hypodermic needle, refill the drug reservoir **104**; 3) a portioning pump **108** used to dispense a precise volume of drug to a catheter **110** by making one or more small injections (portions); 4) a pump inlet tube **112**; 5) a pump outlet tube **114**; 6) the drug delivery catheter **110** which is used to carry and deliver to the target tissue the drug volume dispensed by the pump **108**; and 7) a multi-wire cable **118** which carries the electrical signals for driving the pump **108**.

Referring again to FIG. **3**, the wire conductors **121–123** are used to drive the pump **108** and the wire conductors **131–133** are used to sense when a portion has been delivered. The micro controller **46** measures the time required for delivering each drug portion, and based on this time determines if the pump **108** is empty or contains fluid, since the former condition results is a faster time than the latter. Upon sensing a "pump empty" condition, the micro controller **46** signals the patient, via an audible alarm **140** and/or a vibrating alarm **142**, that the reservoir **104** is empty. It should be noted that the titanium housing **150** of the receiver **14** should be in close proximity to the audible alarm **140** in order to transmit the sound waves to outside the human body.

FIG. **4** is a block diagram of an implantable, rechargeable cardiac pacemaker system. The block diagram for the transmitter **12** is the same as for the block diagram of the transmitter **12** shown in FIG. **1**.

The block diagram for the receiver **14** contains the same power supply system, supply switching means and method for recharging the rechargeable power source **44** that already have been described above in connection with the description of FIG. **1**, but has been modified to incorporate the components required to assemble an implantable, rechargeable cardiac pacemaker system. These components are: 1) a pulse amplitude D/A converter **202** which is used to regulate, under command of the micro controller **46**, the amplitude of the stimulating pulses delivered to the human heart; 2) a bus **204** which carries the binary value for the amplitude from the micro controller **46** to the D/A converter **202**; 3) an amplifier and filter **206** which detects and amplifies the cardiac depolarization waves (such as R or P waves) and filters out other signal frequencies not related to cardiac activity; 4) an implanted lead **210** containing electrodes **211–212** which is used to deliver stimulating pulses to the heart in order to regulate the heart's rhythm, but which is used also to pick-up and carry the cardiac depolarization waves to the amplifier/filter **206**. These cardiac waves are used by the micro controller **46** to measure the intrinsic rate of the heart. The measurement is utilized to determine if electrical stimulation pulses are needed to speed-up the heart.

Upon sensing that the charge in the rechargeable power source **44** is below a predetermined level, the micro controller **46** signals the patient, via an audible alarm **220** and/or a vibrating alarm **222**, that the rechargeable power source **44** should be recharged.

In FIG. **5** is illustrated a block diagram of an implantable, rechargeable cardioverter/defibrillator. The block diagram for the transmitter **12** is the same as the block diagram for the transmitter **12** shown in FIG. **1**.

The block diagram for the receiver **14** contains the same power supply system, supply switching means and method for recharging the rechargeable power source **44** that already have been described above in connection with the description of FIG. **1**, but has been modified to incorporate the components required to assemble an implantable, rechargeable cardioverter/defibrillator system. These components are: 1) a high voltage output, DC to DC converter **302** used to convert the low voltage available at the rechargeable power source **44** to a relatively higher voltage required to cardiovert a fibrillating human heart; 2) a bus **304** which carries the binary value for the voltage amplitude from the micro controller **46** to the D/A converter **302**; 3) an amplifier/filter **306** used to detect the presence of a cardiac arrhythmia such as fibrillation or tachycardia; and, 4) an implanted cardioverting lead **310** containing cardioverting electrodes **311–312**.

As shown in FIG. **5**, the DC/DC converter **302** is used to generate either low voltage pulses to pace the human heart when needed or high voltage pulses to shock a large number of cardiac cells into synchrony, thereby restoring a normal cardiac rhythm. The micro controller **46**, via the bus **304**, regulates the timing and amplitude of low voltage pulses or high voltage shocks, depending if an arrhythmia is detected or not. Upon sensing that the charge in the rechargeable power source **44** is below a predetermined level, the micro controller **46** signals the patient, via an audible alarm **320** and/or a vibrating alarm **322**, that the rechargeable power source **44** should be recharged.

In FIG. **6** there is illustrated a block diagram of an implantable, rechargeable monitor and diagnostic system. The block diagram for the transmitter **12** is the same as the block diagram for the transmitter **12** shown in FIG. **1**.

The block diagram for the receiver **14** contains the same power supply system, supply switching means and method for recharging the rechargeable power source **44** that already have been described in connection with the description of FIG. **1**, but has been modified to incorporate the components required to assemble an implantable, rechargeable monitor and diagnostic system. These components are: 1) an amplifier/filter **406** used to amplify the desired biological signals and to filter out other undesirable signals; 2) an analog to digital converter **408** which is used to convert the biological signal into a digital value representative of frequency and amplitude of the biological signal; 3) a monitoring lead **410** containing electrodes **411–412** which are used to pick-up and carry the biological signals to the amplifier/filter **406**.

The mission of the monitor and diagnostic system shown in FIG. **6** is to monitor and record, in a non-volatile memory **414**, specific biological signals and events occurring adjacent to the monitoring electrodes **411–412**. Later, at a convenient time, these recordings can be telemetered to the transmitter **12** which will produce, via a graphic recorder **416**, a hard copy of the biological signals for the physician's examination and eventual diagnosis. Any time biological signals occur, they are scrutinized by the micro controller **46** for specific morphology which would cause the event to be stored into the memory **27** for later examination by the physician. An example of a typical use, would be to record dysfunctional endocardiac signals which, when inspected by a trained physician, may reveal the origin of a cardiac dysfunction not detected by conventional means, such as a surface EKG.

From the foregoing description, it will be apparent that the RF coupled, implantable medical system **10** with the rechargeable back-up power supply/source **44** of the present invention has a number of advantages, some of which have been described above and others of which are inherent in the invention. Also it will be understood that modifications can be made to the RF coupled, implantable medical system including the rechargeable back-up power supply/source **44** described above without departing from the teachings of the present invention. Accordingly, the scope of the invention is only to be limited as necessitated by the accompanying claims.

We claim:

1. An RF coupled implantable medical system comprising:

a transmitting unit;

a receiving unit including an implantable, electrically operated, medical device, RF energy receiving means, RF signal transmitting means and a rechargeable battery;

said transmitting unit including a power source, RF energy transmitting means, RF signal receiving means and first control means coupled to said RF energy transmitting means and to said RF signal receiving means for controlling the amount of RF energy transmitted to said receiving unit thereby to conserve on the amount of power obtained from said power source;

second control means coupled to said RF energy receiving means, to said rechargeable battery, to said RF signal transmitting means and to said implantable medical device, for adjusting the charging current flowing into said rechargeable battery, as a function of (a) the charge level of said rechargeable battery, (b) selected charging rate, and (c) selected power supply for the implantable medical device.

2. The system of claim **1** wherein said receiving unit includes a titanium housing enclosing said RF energy receiving means, said RF signal transmitting means, said rechargeable battery and said second control means.

3. The system of claim **1** wherein said RF energy transmitting means of said transmitting unit is constructed to transmit energy at a frequency as low as 10 Hz and up to at least 20,000 Hz.

4. The system of claim **1** wherein said rechargeable battery has a temperature sensor which is mounted closely adjacent thereto and which is coupled via said RF signal transmitting means to said first control means of said transmitting unit whereby the level of transmitted RF energy can be reduced proportionally to the reduction in charging rate of the rechargeable battery in said receiving unit, in order to reduce the power consumption from said power source powering said transmitting unit.

5. The system of claim **1** wherein said RF energy transmitting means of said transmitting unit includes mode selection means for recharging said rechargeable battery at a "fast" (high energy) rate or at a "trickle" (low to medium energy) rate.

6. The system of claim **1** wherein said transmitting unit includes power source selection means for setting said receiving unit to obtain its operating power from (1) RF coupled energy ("RF only" mode), (2) said rechargeable battery ("battery only" mode) or (3) automatically switch to "RF only" upon detection of said RF energy field, or "battery only" when said RF energy field is not detected ("combination" mode).

7. The system of claim **6** wherein said receiving unit includes: (a) means for rectifying said RF energy into a relatively high D.C. voltage, (b) means for regulating said high D.C. voltage into a lower D.C. voltage, and (c) means for detecting the presence of said RF energy field,

said receiving unit, when set to operate in said "RF coupled energy" mode, is operable to supply regulated electrical energy to said implantable device so long as said transmitting unit is located proximate to said receiving unit and said receiving unit is sensing transmitted RF energy.

8. The system of claim **6** wherein said receiving unit, when said transmitting unit is set to operate in said "battery only" mode, is operable, periodically, to supply electrical energy to said implantable device from said rechargeable power supply for a period of at least 24 hours.

9. The system of claim **6** wherein said receiving unit, when set to operate in said "combination" mode, is operable to supply regulated D.C. electrical energy to said implantable device, so long as said transmitting unit is located proximate to said receiving unit, and, separately, to "trickle charge" said rechargeable battery to maintain same fully charged.

10. The system of claim **1** wherein said first control means of said transmitting unit includes means for controlling the level of RF energy transfer from the transmitting unit to the receiving unit relative to one or more of one or more of the following parameters: (a) the charge level of said rechargeable battery, (b) selected charging rate, and (c) the selected power supply for said receiving unit.

11. The system of claim **1** wherein said receiving unit comprises means for measuring the charge level of said rechargeable battery and, upon sensing a fully charged battery, automatically up-links a coded signal which commands said transmitting unit to "stop" transmitting RF energy.

12. The system of claim **1** wherein said transmitting unit includes a visual display coupled to said first control means.

13. The system of claim **1** wherein said transmitting unit includes a keyboard coupled to said first control means.

14. The system of claim **13** wherein said keyboard includes keys to start and stop recharging of said rechargeable battery within the implantable medical device.

15. The system of claim **1** wherein said implanted medical device is a tissue stimulator.

16. The system of claim **1** wherein said implanted medical device is a drug delivery system.

17. The system of claim **1** wherein said implanted medical device is a cardiac pacemaker system.

18. The system of claim **1** wherein said implanted medical device is a cardioverter/defibrillator.

19. The system of claim **1** wherein said transmitting unit includes a battery, whereby said transmitting unit is portable and not dependant upon an a.c. power source.

20. The system of claim **19** wherein said battery can be a rechargeable battery or a non-rechargeable battery.

21. The system of claim **1** wherein said RF energy transmitting means of said transmitting unit includes mode selection means for setting said transmitting unit to operate in one of the following modes: "RF only", "battery only" or a "combination of both".

22. The system of claim **21** wherein said RF energy transmitting means of said transmitting unit controls the amount of RF energy transmitted and,

(a) when said implanted receiving unit is set to operate in said "RF only" mode, said transmitted RF energy is automatically adjusted to the amount of RF energy required (i) to operate said implanted device and (ii) to maintain said rechargeable battery, which is powering said implanted device, in a fully charged state;

(b) when said implanted receiving unit is set to operate in said "battery only" mode, said transmitted RF energy is automatically adjusted to the amount of RF energy required (i) to operate said implanted device and (ii) to recharge quickly said rechargeable battery which is powering said implanted device; and,

(c) when said implanted receiving unit is set to operate in said "combination of both" mode, said receiving unit is set to switch automatically to either said "RF only" mode upon detecting said transmitted RF energy, or to said "battery only" mode upon detecting a loss of said transmitted RF energy.

23. An RF coupled implantable medical system comprising:

a transmitting unit;

a receiving unit including an implantable, electrically operated, medical device;

said transmitting unit including RF energy transmitting means, RF signal receiving means and first control means coupled to said RF energy transmitting means and to said RF signal receiving means for controlling the amount of RF energy transmitted to said receiving unit;

said receiving unit including RF energy receiving means, RF signal transmitting means, a rechargeable power supply coupled to said RF energy receiving means and second control means for adjusting the charging current flowing into said rechargeable battery coupled to said rechargeable power supply means, to said RF energy receiving means, to said RF signal transmitting means and to said implanted medical device, and

mode selection means for setting said receiving unit to operate in one of the following modes: (1) "RF only", (2) "battery only" or (3) "combination of both".

24. The system of claim **23** wherein said receiving unit, when said transmitting unit is set to operate in said "RF only" mode, is operable to supply electrical energy to said implantable device, so long as said transmitting unit is located proximate to said receiving unit and said receiving unit is sensing transmitted RF energy.

25. The system of claim **23** wherein said receiving unit, when said transmitting unit is set to operate in said "battery only" mode, is operable, periodically, to supply electrical energy to said implantable device from said rechargeable power supply for a period of at least 7 days.

26. The system of claim **23** wherein said receiving unit, when said transmitting unit is set to operate in said "battery only" mode, is operable, periodically, to supply electrical energy to said implantable device from said rechargeable power supply for a period of at least 24 hours.

27. The system of claim **23** wherein said receiving unit, when said transmitting unit is set to operate in said "combination" mode, is operable to supply electrical energy to said implantable device through a rectifier directly to said implanted medical device, so long as said transmitting unit is located proximate to said receiving unit, and, separately, to "trickle charge" said rechargeable power supply.

28. An RF coupled implantable medical system comprising:

a transmitting unit;

a receiving unit including an implantable, electrically operated, medical device;

said transmitting unit including RF energy transmitting means, RF signal receiving means and first control means coupled to said RF energy transmitting means and to said RF signal receiving means for controlling the amount of RF energy transmitted to said receiving unit;

said receiving unit including RF energy receiving means, RF signal transmitting means, a rechargeable power supply coupled to said RF energy receiving means and second control means for adjusting the charging current flowing into said rechargeable battery coupled to said rechargeable power supply means, to said RF energy receiving means, to said RF signal transmitting means and to said implanted medical device; and,

said receiving unit comprising means for measuring the charge level of said rechargeable battery and, upon sensing a fully charged battery, automatically up-linking a coded signal which commands said transmitting unit to "stop" transmitting RF energy.

(57) **ABSTRACT**

A radio frequency energy harvester harvests RF energy from the environment. The energy harvester may include a local power source. The energy harvester may have an associated crystal radio antenna that harvests AM radio waves ubiquitously. The radio frequency energy harvested may be stored via a super capacitor. The stored energy may power a self-contained processing unit directly when the level of the energy harvested remains above a threshold level. However, if the energy harvested drops below the threshold level, the processing unit, which may include a radio, may switch to the local power source and/or a low power mode of operation. The low power mode of operation may reduce the amount of processing and/or transmitting by the radio. The processing unit may be part of a network of radios. The energy harvester may supply energy for a variety of applications, including building automation, industrial automation, power generation, and healthcare.

PASSIVE RF ENERGY HARVESTING SCHEME FOR WIRELESS SENSOR

PRIORITY AND CROSS-REFERENCE TO RELATED APPLICATION

This application claims priority under 35 U.S.C. §119(e) to provisional application Ser. No. 60/744,028, filed on Mar. 31, 2006, which is incorporated by reference in its entirety herein.

BACKGROUND

The present embodiments relate generally to harvesting environmental energy. More particularly, the present embodiments relate to harvesting energy from radio frequency (RF) signals to power a sensor node and/or wireless radio.

Wireless sensor networks (WSNs) of so-called "smart" sensors can be used in remote monitoring and control applications. However, in almost all applications that involve WSNs, there is a trade off between the need to sense and communicate useful information and the requirement to do so in an energy efficient manner. A WSN, once deployed, may be intended to work for long periods of time with only minimal human intervention. For instance, remote monitoring applications may include individual sensor nodes, numbering into the hundreds or even thousands, that each run on a limited supply of energy, such as a battery. As a result, with conventional sensor nodes, excessive on-board processing and, perhaps more importantly, frequent invocation of the sensor node's radio may rapidly deplete the on-board energy source. Therefore, there is a need to develop sensor network protocols and algorithms with energy-efficient and self-organizing capabilities.

Additionally, replacing depleted batteries may be inefficient or impractical. A network may include a large number of individual sensor nodes that may be difficult to access due to being implanted within a wall, a ceiling, a larger device, or a patient. Accordingly, there is also a need for novel energy harvesting schemes operable to power wireless sensor nodes, as well as automatically replenish on-board energy storage units.

BRIEF SUMMARY

By way of introduction, the embodiments described below include methods, processes, apparatuses, instructions, or systems for harvesting energy from freely available radio frequency (RF) signals. The energy harvested may power processing units, such as self-contained processing units or sensor nodes. A "passive RF energy harvesting system," or "harvesting system," may be connected to a processing unit having a processor and delivers power supply to the processing unit. Each harvesting system may be associated with a crystal radio receiver and/or an all pass or band pass filter operable to harvest energy from all radio frequency bands simultaneously or ubiquitously. As a result, more of the available RF energy may be harvested from the existing electromagnetic signals. The harvesting is ubiquitous since no tuning is required if the harvester is moved from place to place. Most of the RF energy scavenged may be harvested from amplitude modulated (AM) radio signals. The harvesting system may have a super capacitor that temporarily stores the RF energy captured. If the level of RF energy being harvested falls below a threshold level, an interrupt signal may be generated that directs the processing unit to conserve energy. For instance, the processing unit may limit on-board processing or reduce the number and/or strength of signals transmitted via a wireless radio, or both.

In a first aspect, a method harvests passive radio frequency energy. The method includes harvesting radio frequency energy using a crystal receiver. The method also includes powering a processing unit directly from the radio frequency energy being harvested when the radio frequency energy being harvested or an associated signal is approximately equal to or above a threshold level, and alternatively powering the processing unit from an on-board power source when the radio frequency energy being harvested or the associated signal is below the threshold level.

In a second aspect, a method harvests passive radio frequency energy. The method includes harvesting radio frequency energy via a crystal receiver and storing the radio frequency energy harvested on a super capacitor for subsequent use.

In a third aspect, a system harvests passive radio frequency energy. The system includes a network of radios within a building operable to direct the operation of building equipment to control a building environment of a building and at least one radio within the network being a sensor node operable to harvest radio frequency energy via a crystal receiver, the radio frequency energy harvested being used to power the sensor node.

In a fourth aspect, a computer-readable medium having instructions executable on a computer stored thereon is described. The instructions include monitoring for an interrupt signal that is triggered when the radio frequency energy being harvested via a crystal receiver falls below certain threshold, the radio frequency energy being used to at least partially power a sensor node or charge the battery on the harvesting system. The instructions also include automatically reducing the amount of power being expended by the sensor node if the interrupt signal is detected.

The present invention is defined by the claims herein. Nothing in this section should be taken as a limitation on those claims. Further aspects and advantages of the invention are discussed below in conjunction with the preferred embodiments and may be later claimed independently or in combination.

BRIEF DESCRIPTION OF THE DRAWINGS

The components in the figures are not necessarily to scale, emphasis instead being placed upon illustrating the principles of the invention.

FIGS. **1** and **1***a* are system block diagrams of an exemplary passive RF energy harvesting systems;

FIGS. **2** and **2***a* are schematics of additional exemplary passive RF energy harvesting systems;

FIG. **3** is a schematic of an exemplary network of sensor nodes;

FIG. **4** is a block diagram of an exemplary sensor node;

FIG. **5** is a top plan view of an exemplary network of sensor nodes within a building;

FIG. **6** illustrates an exemplary method of harvesting radio frequency energy;

FIG. **7** illustrates an exemplary interrupt handling method; and

FIGS. **8** and **9** illustrate exemplary antennas.

DETAILED DESCRIPTION OF THE DRAWINGS AND PRESENTLY PREFERRED EMBODIMENTS

The present embodiments are directed toward methods, processes, apparatuses, instructions, or systems for harvest-

ing freely available radio frequency (RF) energy from the environment, such as signals generated from amplitude modulated (AM) and frequency modulated (FM) radio stations. The RF energy harvested is used to power a "sensor node." The sensor node may include a processor, a sensor, an actuator, a wireless radio, and/or other components. The sensor node may be part of a network of radios in direct or indirect communication with one another, such as a wireless sensor network (WSN).

The sensor node may have an associated crystal radio receiver. The crystal radio receiver may operate as an all pass filter to harvest energy from all radio frequency bands simultaneously or ubiquitously. As such, more of the available RF energy may be captured for the given electromagnetic signals being received by the sensor node at a specific time.

The energy harvesting system may have an associated super capacitor that temporarily stores the RF energy received or a related signal, such as a voltage, a current, or other electrical parameter or signal associated with the RF energy harvested. In one embodiment, if a voltage associated with the RF energy being harvested falls below a given threshold, an interrupt signal may be generated that directs the sensor node to switch to a "low-power" mode to conserve energy. In low-power mode, the sensor node may reduce the amount of processing that an on-board processor performs. Alternatively or additionally, in low-power mode, the operation of an on-board wireless radio or transmitter may be altered and/or limited. For example, the wake-up period of the sensor nodes may be increased for energy saving purposes. Other manners of reduced sensor node operation may be employed to conserve energy being expended by the sensor node.

I. Crystal Radio Receivers

Generally, the embodiments discussed herein provide energy harvesting or scavenging for sensor nodes and/or wireless sensor networks (WSNs). In particular, AM RF signals may be harvested via crystal radio receivers to provide the primary, or even sole, source of power for the sensor nodes. Other crystal receivers may be used.

Crystal radios were popular by the 1950's, but are now almost obsolete. One of the key features of crystal radios is that they do not require batteries. The earplugs and/or speakers of a crystal radio may be powered solely by amplitude modulated (AM) radio signals. The crystal radio may employ a piezo-electric crystal, dielectric disk, oscillating crystal, or another type of crystal. The crystal may oscillate or vibrate due to the radio frequency signals being received. Exemplary crystal radio receivers are disclosed by U.S. Pat. Nos. 2,554,270, 2,805,332, 3,327,222, and 3,996,522, which are all incorporated herein by reference in their entireties. Other crystal radio receivers may be used.

The crystal radio technology may be used in new applications due to the advancement of semi-conductors and reduced power requirements of sensor nodes. In other words, the available energy that may be harvested from radio frequency signals via a crystal radio receiver, may contain sufficient energy to power milliwatt level instruments and micro-devices. Additionally, the size of a crystal radio antenna may be configured to be relatively small, ranging from a few to tens of centimeters. An antenna of this size may be used with a number of today's wireless sensor node applications.

Harvesting small amounts of energy from radio signals has been studied before, although not in the context of powering nodes in a WSN by AM RF signals. Previous studies have concluded that RF energy is of little utility unless a receiver is very close to a transmitter, such as a cell phone station. An alternate approach would be to introduce an RF signal transmitter for the explicit purpose of transmitting RF energy to a receiver that then harvests the RF energy to perform certain tasks. In other embodiments, such an approach may not be practical in the context of WSNs.

The energy available from RF signals in the unlicensed band, for e.g., the 2.4 GHz spectrum, may be typically too limited to be of any practical use. Such RF power harvesting may be impractical due to (1) very limited power being available (for an antenna size of 100 cm^2, the received power may be less than 0.1 milliwatt), and (2) very limited range (not only may a transmitter be required, but the sensor also may have to be placed very close to the transmitter). On the other hand, the principles on which crystal radios operate may finally permit the successful harvesting of energy from freely available RF signals.

As AM radio signals may be strong enough to power an earplug or a speaker, the energy available from RF signals may be more than past estimates indicated. A typical sensor node may require about 20 milliamps in active mode and 5 microamps in sleep mode, and the operating voltage required may be about 3 volts. Thus, the required power for a typical sensor node is comparable to the power that may be harvested via RF signals. Additionally, low-duty low-energy sensors may not require a transmitter, further reducing the amount of energy needed to power the sensor node. Therefore, RF signals may be a viable "free" and persistent (available 24 hours a day) energy source for a considerable amount of a given radio broadcast receiving area.

II. Estimation of Received Radio Energy

Table 1 below illustrates an estimation of the available RF energy in Princeton, N.J. from AM and FM RF signals transmitted by area radio stations. Through this rough estimation analysis, the "free" RF energy in the Princeton area is shown to be within the 10 milliwatt level. The estimation is based upon the Friis propagation model,

$$P_r = \frac{p_t G_t G_r \lambda^2}{(4\pi)^2 d^2 L},$$

TABLE 1

Here, p_t, p_r are the power of the transmitter and the receiver, respectively; G_t, G_r are the antenna gains of the transmitter and the receiver, respectively; λ is the wavelength of the RF signal in meters; d is the distance between the transmitter and the receiver; and L is the system losses ($L>1$). The estimation is based upon various assumptions, such as (1) radio station information (frequency and distance), (2) the transmitting power of AM radio stations being 10 kilowatt and FM stations being 5 kilowatt, (3) the antenna gains, G, are 1 (for a properly designed antenna, $G>1$), and (4) the system losses, L, are 1.

The results of the estimation indicate that (1) the total power received was 31.120 milliwatts, (2) the AM power received was 31.108 milliwatts, or 99.96% of the total power, and (3) the FM power received was 0.0126 milliwatt, or 0.04% of the total power. The estimation is based on ideal environments. In practice, L is more than 1 and the received power is less than the ideal case. Observing the Friis propagation model reveals that the effect of wavelength on the received power is more than that of the transmission power. Accordingly, signals with longer wavelength, such as AM signals, are much more suitable for RF energy harvesting.

A typical sensor node may require about 41 milliwatts in active mode and 1.5 microwatts in sleep mode. This power requirement is of the same order of magnitude as the power that is available from RF signals. With reasonable conditions, such as the sensor nodes being located near one or more AM radio stations and/or using relatively efficient antennas, the sensor nodes may be powered solely by the AM signal(s) and be kept running uninhibited all of the time. Alternatively, the sensor nodes may be powered primarily by the AM signal(s), if backed up by an on-board energy source.

III. Estimation of Available Energy from Other RF Signal Sources

As noted above, AM signals may include much more energy available for harvesting than FM signals. Energy from other RF signal sources also may be very small when compared with AM signals. For example, the RF signals from cell phones quickly attenuate as a function of distance. As a result, a cell phone signal may be used as a source of energy to power a sensor node only if the distance from the cell phone to the sensor node is about one meter or less.

Energy also may be received from IEEE 802.11.x protocol-based devices and television sets. As IEEE 802.11.x devices operate in the 2.4 GHz band, the energy available for harvesting may be even less than what is available from cell phones. Similarly, due to their high frequency, television signals may contribute very little towards harvestable energy. Therefore, AM signals may provide the best freely available RF source of power for wireless sensor nodes.

IV. Hybrid Scheme

A number of harvesting schemes may be utilized to capture energy from RF signals. As an example, harvesting energy from AM signals may not only be useful for indoor sensor nodes, but could also prove fruitful for outdoor sensor deployments.

In one aspect, the RF harvesting schemes discussed herein may combine two concepts. A sensor node may include crystal radio technology that is operable in conjunction with an energy storage unit, such as a battery and/or a capacitor. Once the output of the crystal radio receiver is connected to act as a source of energy and/or a "charger" to the energy storage unit, the system may be ready for use.

The sensor node may include a RF energy harvesting device that includes a so-called "energy harvesting antenna" operable to capture RF energy. The antenna may harvest AM, as well as FM, or RF signals. The antenna may be a spider antenna, braided antenna, omni-directional antenna, double-braided polyester rope, loop antenna, air coil loop antenna, sparrow antenna, Yagi-Uda antenna, or other type of antenna.

For example, FIG. **8** is an exemplary spider antenna. As shown, the antenna may have a number of legs of differing size. FIG. **9** is another exemplary antenna. Other shapes may be used, such as circular or disk shapes.

The antenna may be a laminated antenna having a number of wires etched onto a semi-conductor or other micro-device. The antenna wires may have either a flat or rounded shape, or be disk shaped. The antenna may have a number of spokes or legs, such as the spider antenna disclosed by U.S. Pat. No. 4,229,742, or the antenna may be a grid antenna similar to the one disclosed by U.S. Pat. No. 7,038,630, both of which are incorporated herein by reference in their entireties. As the antenna characteristics may be determined based upon the bandwidth and gain properties desired for a specific application, alternative antennas may be used.

In one embodiment, for both convenience and cost reduction purposes, a 1950's type of coil or wire antenna connected to the crystal radio receiver may be replaced by modern flexible printed circuit board. Printed circuit board similar to that used in conventional radio frequency identification (RFID) devices may be used. An exemplary RFID antenna is disclosed by U.S. Pat. No. 6,825,754, which is incorporated herein by reference in its entirety. Other types of printed circuit board material and shapes may be used as the antenna.

Once the RF energy is scavenged, the sensor node may regulate the energy within the crystal radio circuit and convert

the RF signals received to a DC signal, such as via a rectifier, without any frequency filtering. As an example, the RF signals harvested may not be filtered via low, high, or band pass filters. After the RF energy harvested passes through the rectifier, the energy may be stored on a super capacitor. However, since the voltage on the two sides of the super capacitor may not satisfy the requirements of the sensor node, a DC/DC converter and/or another capacitor may be employed (such as shown in FIG. **2**, discussed below).

Clean DC power may be available on both sides of the second capacitor. In addition, the DC/DC converter may sample the voltage on the super capacitor, and issue an interrupt to the sensor node once the voltage, which is an indication of the energy being stored and/or harvested, is lower than a certain threshold. The sensor node may then switch to the on-board power source of the harvesting system, such as a battery, a capacitor, or other energy storage device. If the energy being harvested provides a voltage level greater than that of an on-board energy storage device, the energy being harvested may power the sensor node directly, as well as provide a trickle charge to the on-board energy storage device. On the other hand, if the energy being harvested provides a voltage level lower than of the on-board energy storage device, the on-board energy storage device may provide power to the sensor node via a trickle discharge. The harvested RF energy is used to charge the battery under this case.

Therefore, the wireless and self-contained sensor nodes may employ a "hybrid" RF energy harvesting scheme. Each wireless and self-contained sensor node may be equipped with (1) a RE-based energy harvester and (2) an on-board power source. As long as there is enough available power from the RF energy harvester, the sensor node may operate using the RF power. Intermittently, however, the power from the harvester may not be at the threshold required to operate the sensor node. As a result, an interrupt may be generated that switches the sensor node to the on-board power source. The hybrid scheme ensures that the sensor node may be continuously operational while simultaneously greatly lengthening the life-time of the on-board power source.

There are some distinctions between RF energy harvesting as discussed herein and conventional harvesting schemes. With respect to solar cell techniques, the proposed RF harvesting schemes are not affected by the weather or time of day (darkness). The proposed RF harvesting schemes may provide a continuous power supply as most radio stations broadcast around the clock.

Additionally, the proposed RF harvesting schemes may provide more power than solar cells, such as with indoor environments, and at less cost, as typical solar cells may be more expensive than an RF antenna or coil. The costs associated with the proposed schemes may be further reduced if the antenna is implemented using technology similar to that of a RFID tag.

As compared to biomechanics-based harvesting schemes, the proposed RF harvesting schemes may be more suitable for sensor node applications. Conventional biomechanics harvesting methods tend to provide energy on an inconsistent basis and inconveniently toggle sensors periodically to recharge the power source. On the other hand, the proposed RF harvesting schemes may provide a consistent milliwatt-level power source. Toggling may be used with RF harvesting.

With respect to vibration or thermoelectric methods, it may be more difficult to find a vibration or heat source than it is to locate an AM radio station, especially in populated regions of the United States. When a free source is not available, the vibration or thermoelectric based schemes may require an artificial source. In many environments, such as an office or building, installation of such artificial energy sources may not be feasible.

In sum, new RF energy harvesting schemes are described that provide energy to self-contained sensor nodes. The schemes provide an improved crystal radio receiver and harvest AM RF signals as a source of power. The RF harvesting schemes are suitable for indoor applications that involve wireless sensor networks, such as building automation applications.

The RF harvesting schemes may be especially useful in areas having AM stations within about 20 kilometers to satisfy typical sensor node power requirements. However, the effective distance of the harvesting schemes may be extended. The antennas employed may be configured to harvest more energy and provide enhanced gain. Sensor nodes may be configured to be more energy efficient. For example, the sensor nodes may be programmed to operate more efficiently, such as spending more time in various reduced power modes of operation. Additionally, the sensor nodes equipped with RF energy harvesters may be supplemented with other types of energy harvesters, such as solar, piezo-electric, MEMS (micro-electro-mechanical systems), biomechanical, thermoelectric, and other harvesters. The RF harvesting schemes, except for requiring relatively nearby AM radio stations, may have no other substantial apparent limitations, such as the weather, periodic toggling, or other limits.

V. Exemplary RF Energy Harvesting Systems

FIG. **1** illustrates an exemplary passive RF energy harvesting system **100**. The system **100** may include an energy harvesting antenna **102**, a crystal radio receiver **104**, a super capacitor **106**, a DC/DC converter **108**, a sensor node **110**, a local power source **112**, and/or a communication antenna **114**. The system may include additional, fewer, or alternate components.

The crystal radio receiver **104** or crystal set may employ an antenna **102**. The crystal radio receiver **104** may not require a battery or power source except the power received from radio waves via the antenna **102**. The crystal radio receiver **104** may include an antenna wire, a tuning coil of copper wire, a rectifier, and other components. The crystal radio receiver **104** may be a passive radio receiver, not requiring an actively powered amplifier associated with conventional radios. The crystal radio receiver **104** may preserve electrical power from RF signals received via the antenna **102** and convert the RF signals to electronic power. The crystal radio receiver **104** may include various types of antennas and various "low-tech" or traditional electrical circuitry components, such as capacitors, resistors, inductors, and diodes. As such the crystal radio receiver **104** may be simpler and less expensive to manufacture than current "smart" radios, such as cellular phones.

The antenna **102** may be a conventional crystal radio antenna and include copper or silver wire coils, or a ferrite coil. The antenna **102** may be a Yagi, log-periodic, fiberglass, cable, repeater, or other type of antenna, including those discussed elsewhere herein. The antenna **102** may be manufactured from printed circuit board, aluminum, copper, silver, other metals, or other materials. The antenna may omni-directionally collect all of the available AM radio signals currently being received. The shape, size, circumference, and composition of the antenna **102** may be altered for a specific application and/or to enhance the gain associated with the antenna **102**.

The antenna **102** and crystal radio receiver **104** may act independently or in conjunction to harvest RF energy ubiquitously. The crystal radio receiver **104** may require no tuning and resonant with all of the available frequencies. As a result,

energy may be collected simultaneously from a number of radio stations, which may increase the average level of RF energy being harvested. This may be in contrast with typical receivers that may employ RC resonant circuits, which eliminate some RF signals from being harvested. In one embodiment, the antenna may have a physical length of between 10 and 20 cm.

The low power mode may include a number of algorithms and/or software instructions stored in the sensor node that direct the sensor node or an associated processor to conserve or reduce the amount of energy that the sensor node is using. A processing unit on the sensor node may perform reduced or limited processing in low power mode. The radio may change the message routing being employed based upon the amount of RF energy being sensed or harvested. A transmitter may transmit less often in low power mode, or not at all until the level of the RF energy being harvested returns to above a threshold or self-sustaining level. The transmitter may alter the type of signal being transmitted in low power mode. For example, the sensor node may not relay all the received communication packets, and/or the transmitter on the sensor node may transmit at a reduced power level. The transmission at a reduced power level may be intended to only reach the next or closest available sensor node or radio within the network.

The low power mode may include buffering or storing data, instead of constant or even intermittent transmission of information to other sensor nodes. With typical sensor nodes, the operation of the radio and/or transmitting information may require a substantial amount of energy. Therefore, reducing radio transmissions in low power mode may enhance the effectiveness of the RF harvesting schemes discussed herein.

The super capacitor **106** may store the RF energy being harvested. The capacitance of an electrode associated with the super capacitor **106** may be several hundred times the capacitance of a conventional double-layer capacitor. The super capacitor **106** may have one or more electrodes manufactured from titanium, palladium, aluminum, silicon, or other metals. Alternatively, the electrodes may be doped or have titanium, palladium, aluminum, silicon, or other metal coatings. The super capacitor **106** may be similar to those disclosed by U.S. Pat. Nos. 5,585,999 and 5,151,848, which are incorporated herein by reference in their entireties. Alternate types of super or other capacitors may be used.

The DC-to-DC converter **108** may operate to produce an output voltage signal and/or an interrupt signal **116** based upon a signal received from the super capacitor **106** or an electrical parameter of the super capacitor **106** monitored, such as a voltage, current, or other signal. The DC-to-DC converter **108** may be similar to the DC-to-DC converter disclosed by U.S. Pat. No. 6,417,653, which is incorporated herein by reference in its entirety. Alternate DC-to-DC converters may be used.

In one embodiment, the DC-to-DC converter **108** samples the voltage **120** on the super capacitor **106**. The voltage sampled may be a reflection the current level of RF energy being harvested crystal radio receiver **104** and/or stored by the super capacitor **106**. If the voltage sampled falls below a threshold level, such as a level required by the sensor node **110** to operate normally (i.e., with no power operating restrictions), then the DC-to-DC converter may generate a low-power interrupt **116** signal. The sensor node **110** may switch to a low or reduced power operating mode upon the receipt of the low-power interrupt **116**.

The on-board energy storage unit may be a capacitor or battery **112**. The on-board energy storage unit **112** may be on a trickle charge when the voltage sampled **120** from the super capacitor **106** remains above the threshold level (such as the actual battery or capacitor voltage) with the carryover RF energy harvested directly powering the sensor node **110**. Alternatively, the RF energy harvested may be sent directly from the DC-to-DC converter **108** to the sensor node **110** when the level of RF energy being harvested remains at or above the threshold level.

On the other hand, if the low-power interrupt **116** is sent to the sensor node **110**, the sensor node **110** may select **118** or switch to the on-board storage unit **112** as a direct source of power. Alternatively, when the voltage from the DC-to-DC converter falls below the threshold level (such as the actual capacitor or battery voltage), the sensor node **110** may automatically start to be powered by the on-board power storage unit **112** as the storage unit voltage would be higher than the output voltage of the DC-to-DC converter, as can be envisioned by FIG. **1**. Other manners of powering of the sensor node from the super capacitor, either solely or in conjunction with the storage unit, may be used.

The sensor node **110** may be mounted on a device that includes the other components shown in FIG. **1** or be associated with the other components in another fashion. The sensor node **110** may include a communication antenna **114** that provides for wireless communication with other sensor nodes. The sensor node **110** may include the components shown in FIG. **4** and discussed below, in addition to the components illustrated by FIG. **1**. The sensor node may include additional, fewer, or alternate components.

FIG. **1***a* illustrates another exemplary passive RF energy harvesting system **100**. In one embodiment, the system may be targeted to facilitate the powering of sensor nodes in an ad-hoc wireless sensor network. As each sensor node may have communication functionality through an on-board RF module, a message communication subsystem may not be required to be a part of the RF energy harvesting system **100**. Also, the RF energy harvesting system **100** may be purely passive, and thus, no registration with the FCC is required.

As shown in FIG. **1***a*, the system **100** may be connected to the sensor node and its communication antenna. The system **100** may be a band pass and/or all pass filter to match all AM frequencies in order to provide ubiquitous energy harvesting capability and also to harness the maximum available harvestable energy.

As shown in FIG. **1***a*, a super capacitor is introduced as an energy buffer to the rechargeable batteries. Super capacitors have large number of recharge cycles, but limited energy capacity when compared to rechargeable batteries. In one embodiment, since there is bound to be some variation of RF signal strength from time to time and place to place, the harvested RF energy may not be consistent. Thus, as can be seen from FIGS. **1** and **1***a*, harvested energy can be used to power the sensor node or charge the on-hoard power source (such as batteries) on each sensor node. Thus, the demands on recharge cycles of the batteries are relaxed and the battery lifetime may be improved.

FIG. **1***a* also illustrates the interrupt signal. If the harvested RF energy is not enough and falls below a certain threshold, the DC/DC converter (for example, a MAX1674/MAX1675) may trigger the sensor node via an interrupt signal as shown. The processor on the sensor node, upon receiving this interrupt, may measure the voltages of the super capacitor, V1 **122**, and that of the battery, V2 **124**. Depending upon what these measured values are, the sensor node may make intelligent decisions. In one embodiment, the sensor node controls a power switch **126** that is operable to switch between the super capacitor and the batteries as a source of power. An exemplary

flow chart of an interrupt handling process that may be implemented by software on the sensor node is illustrated by FIG. **7**.

FIG. **2** illustrates the circuit exemplary passive RF energy harvesting system **200**. The system **200** may include a crystal radio receiver **202**, an energy harvesting antenna **204**, a DC/DC converter **206**, a voltage output **208**, and an interrupt output **210**. The system may include additional, fewer, or alternate components.

As shown in FIG. **2**, the crystal radio receiver **202** may include a capacitor bank and a rectifier that converts the RF energy being received into a DC signal. The DC signal harvested may be stored upon the super capacitor C**9**. The DC/DC converter **206** may sense the voltage on the super capacitor C**9** and provide an output voltage VCC **210** to the sensor node, as well as the sensor interrupt **210** when the output voltage approximately reaches or falls below a threshold level. The sensor nodes may use RF energy harvesting systems having additional, fewer, or alternate components.

FIG. **2***a* illustrates another embodiment of the circuit of the exemplary passive RF energy harvesting system **200**. With respect to FIG. **1***a*, FIG. **2***a* illustrates in more detail from where V**1** **212** and V**2** **218** may be sensed. V**1** **212** may be sensed from the super capacitor C**2**. V**2** **218** may be sensed from the battery. FIG. **2***a* also shows the power switch **214**. The system may include additional, fewer, or alternate components.

VI. Exemplary Network

FIG. **3** illustrates an exemplary network **300** of wireless radios or sensor nodes **312**. The network **300** may utilize a dynamic routing algorithm that permits data transmitted to travel the shortest distance or link **314** between sensor nodes **312** to a destination, which decreases the required transmission time for a given message, as well as the required power level of that transmission. The destination may be another sensor node **312** or a control radio **316**. Each wireless and self-contained sensor node **312** and control radio **316** may have a dedicated processor, a receiver, and a transmitter. The network **300** may include additional, fewer, or alternate components.

Each sensor node **312** may communicate its associated routing information to every nearby or adjacent sensor node **312** or control radio **316**. After a sensor node **312** receives a data transmission, a processor of the sensor node **312** may determine what to do with that data, including whether to retransmit the data to an adjacent or nearby sensor node **312** or control radio **316**. The base station **316** may function as a network controller that directs the overall operation of the network **300**.

The network **300** may provide continuous communication with otherwise unavailable sensor nodes **312**. For instance, some sensor nodes **312** may become obstructed by obstacles, such as equipment, containers, furniture, or other items, or may fail. However, the network **300** may reconfigure itself around blocked paths by redirecting transmissions from one sensor node to the next until communication with a lost sensor node is re-established. The network **300** also may provide enhanced communication reliability between sensor nodes **312** as a single sensor node **312** may be in direct communication with a number of other sensor nodes **312**, as shown in FIG. **3**.

The network **300** may implement IEEE 802.15.4 protocols. Other protocol standards may be used. The network **300** may operate as a mesh network, as described in more detail below. Alternate control or routing algorithms/instructions may be used.

VII. Control of Building Equipment

One application of the sensor nodes described herein relates to a network that controls building equipment. The network may include multiple sensor nodes, each having a wireless radio, as well as one or more control radios or base stations that direct the network. Each sensor node may be a so-called "smart" sensor node that includes a receiver, a transmitter, a processor, memory, one or more sensors, an actuator, and/or other components. Each sensor node may transmit messages to a control radio acting as network controller. Alternatively, the network controller may be a dedicated processor. The network may have one or more network controllers and/or control radios. The term network herein may include the entire network, a sub-set of a network, a number of sensor nodes, one or more network controllers, one or more control radios, or a combination of sensor nodes with one or more network controllers or control radios.

A network controller may assimilate and analyze a number of messages received from a plurality of sensor nodes. In response to each of the messages received, the network controller may determine that a change in the currently operating building equipment, or the operating modes thereof, is in order. Subsequently, the network controller may transmit a message to one or more sensor nodes that direct the operation of building equipment. Upon receiving the message, a sensor node may alter the operation of building equipment.

The sensors associated with the sensor nodes/wireless radios may monitor specific parameters pertaining to building environmental conditions or specific operating equipment. The actuators associated with the sensor nodes may control the operation of certain building equipment. A sensor node may transmit the value of a parameter sensed by a sensor to the network. In response to the values of the parameters received, the network or another sensor node may automatically alter the operation of building equipment, such as by sending messages that operate the actuators that control the building equipment.

For example, the sensors may be temperature sensors that sense the temperature in an area of a building. Each temperature sensor may be connected with a sensor node having a wireless radio, the sensor nodes being dispersed throughout a building. Each sensor node having a temperature sensor may transmit a message to the network regarding the temperature sensed in the building area in which the sensor node is located. In response to the temperature information received, the network may direct that cooling, heating, ventilation, HVAC, emergency, or other building equipment be operated to alter the building environment of the building area in which the sensor node is located.

The network may employ multiple sensor nodes in each building area to monitor temperature. Conventional wall mourned temperature sensors and/or thermostats may be single point sources of information. However, the average value of individual temperature parameters received from a plurality of temperature sensors dispersed in a given building area may better reflect the actual temperature in the building area. Accordingly, the building environmental equipment may be directed to maintain the temperature of a building area closer to the desired temperature based upon the more accurate temperature information received.

The sensors also may be motion sensors that sense motion in a building area. Each motion sensor may be connected with a sensor node having a wireless radio, the sensor nodes being dispersed throughout a building. Each sensor node having a motion sensor may transmit a message to the network regarding the motion sensed in a building area. In response to the motion information received, the network may direct the operation of building equipment.

The motion detected may alert the network that a building area has recently become occupied or unoccupied. In response, the network may ensure that lighting equipment provides adequate light in or near the building area in which motion was sensed. The network may direct that building environmental equipment, such as cooling, heating, ventilation, HVAC, or other equipment, be operated to alter the building environment of the building area. The motion information received also may be used by the network to determine that a security breach has occurred. Accordingly, the network may trigger an alarm, secure passageways, and operate other security equipment in response to the security breach.

A sensor node having a wireless radio may be connected with an identification device located on an individual. After the sensor node located on the identification device transmits a message to the network, the network may determine the identification and/or location of the associated individual. In response, the network may transmit instructions to building environmental equipment to automatically alter the environmental conditions of the specific building area in which the individual is currently located based upon stored or transmitted environmental preferences associated with that individual.

In a building having numerous pieces of operating equipment, it may be desirable to automatically monitor various parameters associated with various pieces of equipment. For instance, in a power plant, refinery, factory, or other plant, it may be advantageous to monitor temperatures, pressures, alarms, tank levels, bilge levels, hydraulic levels, atmospheric conditions, operating pumps or fans, and other parameters. The change in various temperatures, pressures, levels, or equipment operating temperatures may indicate problematic conditions.

The network may automatically identify problematic conditions associated with operating building equipment. The various parameters monitored each may be sensed by a sensor located on a sensor node. The sensor node having a wireless radio may transmit the value of the parameter to the network, either periodically or upon being queried by the network or sensing an out of specification value. The sensor node may determine whether a parameter is within specification, i.e., a predetermined satisfactory range.

If a parameter is not within specification, the network may take corrective action to restore the parameter and/or building conditions to specification. For example, the running speed of a problematic piece of equipment may be shifted, increased, or decreased. The problematic piece of equipment also may be secured and an alternate piece of equipment may be started or placed on line to replace it. Additional, fewer, or alternate courses of action may be taken to correct problematic or out of specification parameters. Sensor nodes may be connected with or part of the equipment being controlled for wireless control of the equipment.

VIII. Mesh Network

In one embodiment, the network may include a number of sensor nodes, each having a wireless radio, arranged as a mesh network that also may be used to locate movable assets and/or operate building environmental equipment. The mesh network provides the capability of routing data and instructions between and among the network of radios. The mesh network permits data to be efficiently transmitted from one radio in the network to the next until the data reaches a desired destination.

The mesh network may be implemented over a wireless network or partially wireless network. Each sensor node having a radio within the network may function as a repeater that transmits data received from adjacent sensor nodes having radios to other nearby sensor nodes that are within range. The coverage area of the mesh network may be increased by adding additional radios. As a result, a network may be established that may cover an area of desired size, such as a floor of a building or an entire building.

Each sensor node having a radio within the mesh network is typically only required to transmit data as far as the next sensor node having a radio within the network. Hence, if a sensor node having a wireless radio has a limited power supply, the reduction in the distance that each sensor node is required to transmit permits lower power level transmissions, which may extend the operating life of the on-board power supply.

A number of protocols may be used to implement the mesh network. The sensor nodes may implement a protocol that uses low data rates and low power consumption. As noted above, the mesh network may employ devices that use very small amounts of power to facilitate significantly increased battery or power supply life. In some situations, power supply life may be extended by minimizing the time that the radio device of the sensor node is “awake” or in normal power using mode, as well as reducing the power at which a signal is transmitted.

Alternatively, the sensor nodes having wireless radios may implement a protocol that uses moderate or high data rates and power consumption. For instance, the sensor nodes may implement IEEE 802.11 protocols. An IEEE 802.11 LAN may be based on a cellular architecture where the system is subdivided into cells, where each cell is controlled by a base station. Other protocols may be implemented.

Additionally, by reducing the distance between sensor nodes, each sensor node having a wireless radio may be able to transmit signals at a reduced power level, which may extend the life of a power supply while the signals transmitted remain strong enough to reach an adjacent sensor node having a radio. The sensor nodes within the network may be synchronized such that each sensor node talks or listens at a particular time. Alternatively, one or more control radios may be generally active, while the remaining radios remain predominantly passive. The control radios may be hardwired directly to a power supply such that they are not confined by a limited power supply.

The mesh network may utilize the Zigbee protocol or other IEEE 802.15.4 Low-Rate Wireless Personal Area Network (WPAN) standards for wireless personal area networking. Zigbee is a published specification set of high level communication protocols designed for use with small, low power digital radios based upon the IEEE 802.15.4 standard. Other IEEE 802.15 standards also may be implemented, including those using Bluetooth or other WPAN or WLAN protocols or any other protocol.

The mesh network of sensor nodes may employ a dynamic routing algorithm. As a result, the mesh network may be self configuring and self mending. Each sensor node within the network may be able to identify neighboring sensor nodes. After receiving a message, a receiving sensor node may determine that it is not the sensor node closest to the destination and/or that it should not relay the message to another sensor node based upon the currently known configuration of operating sensor nodes. The receiving sensor node may wait a predetermined period and listen for another sensor node with a radio to relay the message. If after a predetermined time, the sensor node determines that the message has not been relayed as expected, the receiving sensor node may transmit or relay the message to a nearby sensor node.

By transmitting messages to only reach nearby or adjacent sensor nodes in the network, the messages within the network

may be transmitted at lower power. The low power transmission requires less energy from the on-board power supply of each sensor node. Additionally, the low power transmissions by the sensor nodes prevent one message from occupying the entire network and permits messages to be simultaneously transmitted from different sensor nodes and travel throughout the network of sensor nodes in parallel.

IX. Exemplary Sensor Nodes

FIG. **4** illustrates an exemplary sensor node or wireless radio **410**. The sensor node **410** includes a processor **412**, a wireless radio frequency transmitter and/or receiver **414**, a sensor **416**, an actuator **418**, a memory **420**, a clock **422**, a speaker **424**, a microphone **426**, and an on-board power supply **428**. The sensor node **410** may include additional, different, or fewer components.

For example, the sensor node **410** may be free of the sensor **416**, actuator **418**, memory **420**, clock **422**, speaker **424**, the microphone **426**, and/or power supply **428**. The sensor node **410** may include the processor **412** and the wireless transmitter and/or receiver **414**. For instance, the sensor node **410** may comprise the processor **412**, the wireless radio frequency transmitter and/or receiver **414**, the sensor **416**, the actuator **418**, and the power supply **428**. Or the sensor node **410** may comprise the processor **412**, the wireless radio frequency transmitter and/or receiver **414**, the sensor **416**, and the power supply **428**. The sensor node **410** may include other combinations employing additional, different, or fewer components.

In one embodiment, the sensor node **410** may be operable to automatically control building equipment and locate movable items within a building. In another embodiment, the sensor node **410** may be portable, such as in the case of being mounted upon a movable item, or affixed at a specific location or to an immovable item. The sensor node **410** may be a controller, actuator, sensor, locator or other device in a security, fire, environment control, HVAC, lighting, or other building automation system. The sensor node **410** may determine its present location, sense conditions within a building, report conditions within a building, generate a signal representative of a building condition, and/or respond to an interrogator. The sensor node **410** also or alternatively may actuate building control components. As a controller, the sensor node **410** may be free of the sensor **416** and/or the actuator **418**. In another embodiment, the sensor node **410** is a wireless device free of wired connections to other devices making the sensor node **410** self-contained and/or portable.

The sensor **416** may be a single sensor or include multiple sensors. The sensor **416** may be a temperature, pressure, humidity, fire, smoke, occupancy, air quality, flow, velocity, vibration, rotation, enthalpy, power, voltage, current, light, gas, CO_2, CO, N_2, O_2, chemical, radiation, fluid level, tank level, motion, Global Positioning System (GPS), infrared, or other sensor or combination thereof. The sensor **416** also may be a limit or proximity switch. Alternate sensors may be used.

The sensor **416** may be a motion sensor that detects when a portable sensor node **410** is moving. If it is sensed that the sensor node **410** is moving, the processor **412** may wake the sensor node **410** up from a sleep mode that draws less energy from the power supply **428**. Upon waking up, the sensor node **410** may transmit via the wireless transmitter **414** to the network a message indicating that sensor node **410** is moving.

The sensor **416** may be motion sensor that detects when there is movement within a predetermined distance. For example, the sensor **416** may be wall mounted to detect when an individual has entered a specific building area. If the building area was previously unoccupied, the sensor node **410** on which the sensor **416** is mounted may transmit a message to the network that the building area is no longer unoccupied. As a result, the network may direct that the environmental conditions be altered accordingly, such as increase the temperature during cold weather, decrease the temperature during hot weather, turn on one or additional lights, or adjust the room to the individual's personal preferences.

The sensor **416** may be a GPS unit capable of receiving GPS signals and determining the location of the sensor node **410**. The GPS unit may be able to determine the latitudinal and longitudinal coordinates, as well as the elevation, of the sensor node **410**. The location of the sensor node **410** determined by the GPS unit may be subsequently transmitted to the network via the wireless transmitter **414**.

The actuator **418** may be a single actuator or include multiple actuators. The actuator **418** may be a valve, relay, solenoid, speaker, bell, switch, motor, motor starter, turbine generator, motor generator, diesel generator, pneumatic device, damper, or pump actuating device or combinations thereof. For example, the actuator **412** may be a valve for controlling flow of fluid, gas, or steam in a pipe, or a damper controlling or redirecting air within an air duct. As another example, the actuator **412** may be a relay or other electrical control for opening and closing doors, releasing locks, actuating lights, or starting, stopping, and shifting motors and pumps. As a further example, the actuator **412** may be a solenoid that opens or closes valves, dampers, or doors, such as for altering the flow of fluid or air within piping or ducting. Alternate actuating devices also may be used.

The sensor node **410** may function as a controller or base station. The controller may be positioned at either a known or an unknown location. As a controller, the sensor node **410** interacts with other sensor nodes **410** for control or reporting functions.

The processor **412** is capable of processing data and/or controlling operation of the sensor node **410**. The processor **412** may be a general processor, digital signal processor, application-specific integrated circuit (ASIC), field programmable gate array, analog circuit, digital circuit, network of processors, programmable logic controller, or other processing device. The processor **412** may have an internal memory.

The sensor node **410** also may have a memory unit **420** external to the processor **412**. The memory unit **420** may store data and instructions for the operation and control of the sensor node **410**, such as discussed herein. Additional or alternate types of data also may be stored in the memory unit **420**.

A program may reside on the internal memory or the memory unit **420** and include one or more sequences of executable code or coded instructions that are executed by the processor **412**. The instructions may include monitoring a signal associated with radio frequency energy being harvested via a crystal radio receiver, the radio frequency energy being used to at least partially power a sensor node. The instructions also may include automatically reducing the amount of power being expended by the sensor node if the magnitude of the signal monitored approximately reaches or falls below a threshold level. The instructions may include directions to accomplish other functionality described herein.

The program may be loaded into the internal memory or memory unit **420** from a storage device. The processor **412** may execute one or more sequences of instructions of the program to process data. Data may be input to the data processor **412** with a data input device and/or received from a network. The program and other data may be stored on or read from machine-readable medium, including secondary storage devices such as hard disks, floppy disks, CD-ROMS, and

DVDs, or other forms of machine readable medium, either currently known or later developed.

The processor **412** is capable of directing the transmission or reception of data by the wireless transmitter or receiver **414**, the speaker **424** or the microphone **426**. For example, the processor **412** may direct the acoustic speaker **424** to transmit an ultrasound signal. The processor **412** may also direct the microphone **426** to receive an ultrasound signal and determine a distance from another device as a function of the received signal. Alternatively or additionally, the processor **412** may direct the wireless transmitter or receiver **414** to transmit data for determining the distance. Additionally or alternatively, the wireless transmitter **414** transmits a determined distance or distances as well as data regarding the processes and operation of the sensor **416** and/or the actuator **418**.

The wireless transmitter and receiver **414** or the speaker **424** may be alternate wireless transmitters capable of transmitting a signal for distance determination. Similarly, the wireless receiver **414** and microphone **426** may be alternative wireless receivers capable of transmitting a signal for distance determination.

FIG. **5** illustrates a floor layout for a network of sensor nodes having wireless radios **510** operating with one or more control radios **522** within a building **524**. The sensor nodes **510** may be dispersed throughout the building **524**. One or more of the sensor nodes **510** may be located in each room or other building area. Alternate dispersed arrangements of the sensor nodes **510** may be provided. While one control radio **522** is shown, a plurality of control radios **522** may be provided in other embodiments. Additional, different or fewer sensor nodes **510** and control radios **522** may be provided. While shown as a single floor of a building **524**, the network of sensor nodes **510** and control radios **522** may be distributed over multiple floors, a portion of the floor, a single room, a house, a structure, or any other building **524** or portion thereof.

The various sensor nodes **510** may be of the same configuration or a different configuration than each other. For example, some of the sensor nodes **510** may correspond to sensor arrangements, while other sensor nodes **510** may correspond to actuator arrangements. The same or different communication device, such as a wireless radio frequency transmitter and/or receiver, may be provided for each of the sensor nodes **510**. Alternatively, different communications mechanisms and/or protocols are provided for different groups of the sensor nodes **510**. The sensor nodes **510** may operate in an integrated manner for implementing one or multiple types of building automation control. Alternatively, different networks may be provided for different types of building automation, such as security, HVAC, heating, ventilation, and fire systems.

The sensor nodes powered by RF energy as discussed herein may be useful for a wide variety of applications, in addition to the building control functionality described above. For instance, the applications may include environmental and human body monitoring to military surveillance, building automation, and industrial monitoring. Each sensor node may facilitate one or more control, homeland security, reconnaissance, or other tasks. In one embodiment, the sensor node may be implanted internally within a patient, and sense and transmit data pertaining to a biological characteristic of the patient. The sensor nodes may be used for other applications.

X. Exemplary Method

FIG. **6** illustrates an exemplary RF energy harvesting method. The method may include harvesting RF energy **602**, storing the RF energy harvested **604**, monitoring a signal associated with the RF energy harvested **606**, and selecting an operating mode based upon the level of the signal monitored **608**. The method may include additional, fewer, or alternate actions.

The method may include harvesting RF energy **602**. RF energy may be harvested via a crystal radio receiver as discussed herein. Most of the energy harvested may be scavenged from AM radio signals. The RF energy may be harvested ubiquitously. The RF energy may be used to primarily or solely power a self-contained sensor node.

The method may include storing the RF energy harvested **604**. The RF energy or an associated signal may be measured from a super capacitor or other energy storage means. In one aspect, the RF energy harvestor may be used in unison with another type of energy harvester, such as a solar, biomechanical, thermoelectric, or vibration driven device.

The method may include monitoring a signal associated with the RF energy **606**. A voltage on the super capacitor may be monitored. Other signals related to the RF energy harvested also may be monitored.

The method may include selecting an operating mode based upon the level of the signal monitored **608**. The operating mode selected may relate to power constraints imposed upon the sensor node. If the level of the signal being monitored, such as a voltage signal or other signal, falls below a threshold level, the sensor node may be directed to operate in a low power mode, as discussed herein, to conserve energy until the amount of RF energy being harvested returns to a self-sustaining level with respect to the operating power requirements of the sensor node.

XI. Exemplary Method

FIG. **7** illustrates an exemplary interrupt handling method **700**. The method **700** may be implemented by software on the sensor node. As shown, the method **700** may use a state variable K having 2 states. When K=1, the power switch in FIG. **2***a* may connect pin A to pin Out, which in turn is connected to the pin labeled VCC. The voltage of pin VCC, which is connected to the sensor node, is equal to the output voltage of the DC/DC converter. Thus, in this case, the sensor node is powered through the energy harvester via the super capacitor and DC/DC converter. On the other hand, when K=2, the power switch connects pin B to pin Out and in this case, the sensor node is powered by the battery.

Ts in FIG. **7** is the wake-up period (which is configurable through software depending upon the application). The sensor node wakes up repetitively with time period of Ts. Each time when the sensor node wakes up, it may sense the environment, process the data, and transmit the date to the sink, if necessary. Then the sensor node may enter sleep mode, which costs almost no energy.

Tm in FIG. **7** is the maximum wake-up period allowed by the system. If Ts>Tm, the wake-up period is longer than the upper limit required by the system. Thus, the sensor node cannot provide spontaneous samples to satisfy the quality of service (QoS) requirements of the network.

Tp in FIG. **7** denotes a continuous block of time during which harvested energy is enough to support the continuous operation of the sensor node to execute for a time Te, which is the minimum time required by a sensor node to complete sensing tasks as required by an application. In other words, each time the sensor node wakes up, it may have to execute for at least a period of Te. And the sensor node may have to make a decision as to whether it powers itself from the energy harvester or through the battery for this amount of time. The

following brief analysis is presented to describe the novel sensor node operation that may be facilitated through the energy harvesting circuit.

Let the capacity of the super capacitor be represented by C. Then, the instantaneous energy E stored in the super capacitor is given by:

$$E=\frac{1}{2}CV_1^2.$$

If power rating of the sensor node is P, then the following equation holds

$$E+D'T_p=PT_e,$$

where E' is the derivative of E with respect to time Thus,

$$\begin{aligned} T_p &= \frac{PT_e - E}{E'} \\ &= \frac{PT_e - \frac{1}{2}CV_1^2}{CV_1V_1'}, \end{aligned}$$

where V_1' is the derivative of V**1** and V_1' can be estimated in practice by taking the difference of the V**1** values at consecutive time intervals.

The flow chart shown in FIG. **7** may be described as follows. After receiving the interrupt **702**, the sensor node sends a control signal to the power switch such that the sensor node is powered through the battery **704**, since the energy on the capacitor may be depleted soon. The voltages V**1** and V**2** are measured by the sensor node **706**. Tp is also computed based on V**1** **708**, as shown in the above equation.

V**2** is checked to see if it is low **710**. If it is, then all of the energy is going to be depleted soon. Recall that when the interrupt occurred, V**1** is already low. Thus, in this case, neither the energy harvester nor the battery can power the sensor node. The sensor node must take emergency actions, such as backup data **712** and notify its neighbors **714**. Finally, the sensor node sets Ts to be equal to Tp **716**, as well as sets K to 1 **718**. The rationale being that since the energy in the battery is going to be depleted soon, the node should wait in sleep mode **732** until enough energy has been harvested by the RF energy harvester.

When V**2** is not low, the decision is based on V**1**. If V**1** is low such that Tm≤Tp **720**, which means that the energy harvester cannot satisfy the sensor node energy requirements, then the sensor node once again has no choice but to use power from the battery source. Since there is enough battery energy (recall that V**2** is not low), the sensor node can be powered by the battery **728** through the current wake-up period Ts **726**. The neighbors also may be notified **730**. However, note that the energy from the harvester can still be used to charge the battery through the DC/DC converter. Thus, the system still benefits from the energy harvester even though the node is not powered directly by the energy harvester.

If V**1** is high enough to support the minimal energy requirements of the sensor during its wake-up period, i.e., Tm>Tp, then the sensor node can increase its wake-up period. In this case, Ts is set to be Tp **722** and the sensor node is powered by the energy harvester through the DC/DC converter **724**.

To summarize, the embodiments discussed herein facilitate the following complex sensor node behaviors: (1) switching the operating mode on the sensor node, such as standby or sleep modes; (2) sending a notification message to a sink via other sensor nodes; (3) saving important data to the flash memory on the sensor node, in case it is lost; (4) changing a sampling rate and transmission rate, and reducing the rates according to the voltages V**1** and V**2**, (5) adjusting an energy weighting factor in the network routing metric (if the voltages of the sensor node are not high enough, the use of this node as a router to route other wireless message packets is minimized or avoided), and (6) switching the input power source from the RF energy harvester to a battery.

The methods and systems discussed herein may use one, two, or more antennas. If two antennas are used, one antenna may be dedicated to the sensor node or communications unit, and the other antenna may be dedicated to the RF energy harvesting system, such as shown in the Figures. As both the sensor node and the energy harvester each may have their own dedicated antenna, switching a single antenna between the sensor node and the energy harvester may be alleviated.

The operational mode of the harvesting system and/or the sensor node may be switched by the sensor node itself. Additionally or alternatively, the RF energy harvester discussed herein may trigger the sensor node and provide voltage measurements. For energy conservation purposes, the harvesting system discussed herein may not switch operation modes based on. RF signals.

Therefore, the RF energy harvesters described herein may be directly connected to sensor nodes, purely passive and not needing to pass FCC requirements, and/or based on a band-pass or all pass filter for ubiquitous and wide spectrum RF energy harvesting. The systems discussed herein may facilitate advanced sensor behaviors. The system modes (active, standby and sleep) may be triggered by an interrupt signal and controlled by the sensor node, as compared to altering the operating mode according to received RF signals. The designs of the energy harvesting antenna may be different from known antennas. A super capacitor and/or a DC/DC converter may be employed by the energy harvester. Based on efficiency, size, and costs, the DC/DC converter may be provide benefits as compared to transformers. A buffered energy storage system may be constructed by the super capacitor and one or more rechargeable batteries. The harvesting system may improve battery life time.

While the invention has been described above by reference to various embodiments, it should be understood that many changes and modifications can be made without departing from the scope of the invention. The description and illustrations are by way of example only. Many more embodiments and implementations are possible within the scope of this invention and will be apparent to those of ordinary skill in the art. The various embodiments are not limited to the described environments, and have a wide variety of applications including integrated building control systems, environmental control, security detection, communications, industrial control, power distribution, and hazard reporting.

It is intended in the appended claims to cover all such changes and modifications which fall within the true spirit and scope of the invention. Therefore, the invention is not limited to the specific details, representative embodiments, and illustrated examples in this description. Accordingly, the invention is not to be restricted except in light as necessitated by the accompanying claims and their equivalents.

We claim:

1. A method of passive radio frequency energy harvesting, the method comprising:

harvesting radio frequency energy using a crystal receiver;

powering a processing unit only from the radio frequency energy being harvested when the radio frequency energy being harvested, or an indication of the amount of radio frequency energy being harvested, is above a threshold level;

generating an interrupt signal to switch the processing unit to a low power mode when the radio frequency energy

being harvested, or the indication of the amount of radio frequency energy being harvested, falls below the threshold level; and

alternatively powering the processing unit only from an on-board power source when the radio frequency energy being harvested, or the indication of the amount of radio frequency energy being harvested, is below the threshold level.

2. The method of claim **1**, wherein the crystal receiver employs an antenna that is fabricated from printed circuit board.

3. The method of claim **1**, wherein the radio frequency energy harvested is increased by a super capacitor before being used to power the processing unit.

4. The method of claim **1**, wherein the on-board power source is a battery or a capacitor.

5. The method of claim **1**, wherein the crystal receiver employs a ferrite coil antenna.

6. The method of claim **1**, wherein the radio frequency energy is harvested ubiquitously.

7. A method of passive radio frequency energy harvesting, the method comprising:

harvesting radio frequency energy using a crystal receiver;

powering a processing unit only from the radio frequency energy being harvested when the radio frequency energy being harvested, or an indication of the amount of radio frequency energy being harvested, is above a threshold level, wherein the processor unit is a self-contained sensor node operable to direct the operation of building equipment to control an environment of a building;

generating an interrupt signal to switch the processing unit to a low power mode when the radio frequency energy being harvested, or the indication of the amount of radio frequency energy being harvested, falls below the threshold level; and

alternatively powering the processing unit only from an on-board power source when the radio frequency energy being harvested, or the indication of the amount of radio frequency energy being harvested, is below the threshold level.

8. The method of claim **7**, wherein the processor unit has power requirements of greater than 10 milliwatts.

(57) **ABSTRACT**

Disclosed is an apparatus for an application including a core device for the application. The apparatus includes a power (preferably RF energy) harvester connected to the core device to power the core device. Also disclosed is a method for an application. The method includes the steps of converting RF energy into usable energy. There is the step of powering the core device with the usable energy.

POWERING DEVICES USING RF ENERGY HARVESTING

This application claims priority to and is a divisional application of U.S. patent application Ser. No. 11/447,412, filed Jun. 6, 2006, now abandoned and entitled "POWERING DEVICES USING RF ENERGY HARVESTING," which claims priority to U.S. Provisional Patent Application No. 60/688,587, filed on Jun. 8, 2005, and entitled "POWERING DEVICES USING RF ENERGY HARVESTING;" both of which are incorporated herein by references in their entireties.

FIELD OF THE INVENTION

The present invention is related to the wireless powering of devices. More specifically, the present invention is related to the wireless powering of devices with a power harvester.

BACKGROUND OF THE INVENTION

As processor capabilities have expanded and power requirements have decreased there has been an ongoing explosion of devices that operate completely independent of wires or power cords. These "untethered" devices range from cell phones, and wireless keyboards to building sensors and active RFID tags.

Engineers and designers of these untethered devices continue to have to deal with the limitations of portable power sources, primarily batteries as the key design parameter. While performance of processors and portable devices have been doubling every 18-24 months driven by Moore's law, battery technology in terms of capacity has only been growing at measly 6% per year. Even with power conscious designs and the latest in battery technology, many devices do not provide the lifetime cost and maintenance requirements for applications that require a large number of untethered devices such as logistics, and building automation. Today's devices that need two-way communication require scheduled maintenance every three to 18 months to replace or recharge the device's power source (typically a battery). One-way devices simply broadcasting their status (one-way) such as automated utility meter readers have a better battery life, typically requiring replacement within 10 years. For both device types, scheduled power-source maintenance is costly and disruptive to the entire system that a device is intended to monitor and/or control. Unscheduled maintenance trips are even more costly and disruptive. On a macro level, the relatively high cost associated with the internal battery also reduces the practical, or economically viable, number of devices that can be deployed.

The ideal solution to the power problem for untethered devices is a device or system that can collect and harness sufficient energy from the external environment. The harnessed energy would then either directly power an untethered device or augment a battery or other storage component. Directly powering an untethered device enables the device to be constructed without the need for a battery. Augmenting a storage component could be along two lines: 1) increasing the overall life of the device or 2) by providing more power to the device to increase the functionality of the device. The other parameters for an ideal solution is that the harnessing device could be used in a wide range of environments including harsh and sealed environments (e.g. nuclear reactors), would be inexpensive to produce, would be safe for humans, and would have a minimal effect on the basic size, weight and other physical characteristics of the untethered device.

BRIEF SUMMARY OF THE INVENTION

The present invention pertains to an apparatus for an application. The apparatus comprises a core device preferably having an integrated circuit for the application. The apparatus comprises a power harvester (preferably a radio frequency (RF) energy harvester) connected to the core device to power the core device.

The present invention pertains to an apparatus for an application. The apparatus comprises a core device preferably having an integrated circuit for the application. The apparatus comprises means for receiving energy wirelessly and providing power from the energy to the core device to power the integrated circuit of the core device. The receiving means is connected to the core device.

The present invention pertains to a method for an application. The method comprises the steps of converting RF energy into usable energy. There is the step of preferably powering an integrated circuit of the core device with the usable energy.

This invention pertains to a technique that uses radio frequency (RF) energy as a source of energy to directly power a device or augment a power storage component in a device. The present invention meets the requirements described in the previous "Background of the Invention" section.

Traditional RF receiving devices have focused on maximizing selectivity of the frequency to isolate and to be coherent without interference from other sources. In contrast, while the present invention operates at a specific frequency or range of frequencies, the device accepts any interference to supplement the output power of the device. Also, the research related to power harvesting that uses RF energy as a source has primarily focused on devices in close proximity of the source (inductive or near-field energy). In most cases, prior research assumed a dedicated or directed source of RF to power the device.

The invention should not be confused with power transfer by inductive coupling, which requires the device to be relatively close to the power transmission source. The RFID Handbook by the author Klaus Finkenzeller defines the inductive coupling region as distance between the transmitter and receiver of less than 0.16 times lambda where lambda is the wavelength of the RF wave. The invention can be implemented in the near field (sometimes referred to as inductive) region as well as the far-field region. The far-field region is distances greater than 0.16 times lambda.

It is an object of this invention to provide a method and apparatus to

1. remotely energize an untethered device without using direct wiring
2. power or augment the life of the power storage component so it matches the life of the device and, ultimately, powers the off-grid device with or without the use of batteries
3. allow untethered devices to be virtually maintenance free
4. provide augmentation for other energy harvesting technologies (solar, piezoelectric, etc.)
5. provide backup power to tethered devices

It is a further object of this invention to directly power a device or augment a power storage component in a device in conjunction with other power harvesting technologies and storage elements.

With this method and apparatus a device's power storage components do not require replacement, thus enabling the device to be permanently placed off-grid, where it may be physically impractical, costly, or dangerous (due to a harsh environment) to provide maintenance.

For devices on-grid (tethered) or with reliable power sources, RF power harvesting can be used as a backup in case the primary power source is lost.

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWING

In the accompanying drawings, the preferred embodiment of the invention and preferred methods of practicing the invention are illustrated in which:

FIG. **1** is a block diagram of an RF Power Harvesting block used to directly supply power to Core Device Components.

FIG. **2** is a block diagram of an RF Power Harvesting block in communication with a Power Regulation and/or Power Storage Circuit.

FIG. **3** is a block diagram of an RF Power Harvesting block in communication with a Power Regulation and/or Power Storage Circuit and used to supply power to Core Device Components.

FIG. **4** is a block diagram of an RF Power Harvesting block in communication with a Power Regulation and/or Power Storage Circuit.

DETAILED DESCRIPTION OF THE INVENTION

A complete understanding of the invention will be obtained from the following description when taken in connection with the accompanying drawing figures wherein like reference characters identify like parts throughout.

There is shown an apparatus **10** for an application. The apparatus **10** comprises a core device **22** preferably having an integrated circuit **36** for the application. The apparatus **10** comprises a power harvester **20** connected to the core device **22** to power the core device **22**.

The apparatus **10** preferably includes an alternative power source **24** connected to the core device **22** to power the core device **22** in conjunction with the power harvester **20**. Preferably, the apparatus **10** includes a power regulator **26** and/or power storage circuit **28** connected to the power harvester **20**. The apparatus **10** preferably includes a power storage charger **30** connected to the power harvester **20**. Preferably, the apparatus **10** includes a power storage connected to the power harvester **20**.

Preferably, the core device **22** includes a memory **38** connected to the integrated circuit **36** and to the power harvester **20** to power the memory **36**.

The core device **22** can include a sensor **32**, as shown in FIG. **89**. The sensor **32** can include a proximity sensor, an intrusion sensor, an environmental sensor, a chemical sensor, a biological sensor, a sensor in contact with an automobile, an occupancy sensor, a motion sensor, a position sensor, a metal detector, or a sensor **32** in contact with an aircraft. The sensor **32** can include an alarm connected to the power harvester **20** to power the alarm, a display connected to the power harvester **20** to power the display, a sensor **32** disposed in a building, an industrial automation sensor, a sensor **32** in contact with an elevator, a temperature sensor, a fire sensor, or an accelerometer.

The sensor **32** can include a level sensor, a gas level sensor, a fluid level sensor, a light level sensor. The sensor **32** can include a flow sensor, a gas flow sensor, a fluid flow sensor, a light flow sensor, or a plasma flow sensor.

The sensor **32** can include a pressure sensor, a gas pressure sensor, a fluid pressure sensor, a light sensor, an infrared light sensor, an ultraviolet light sensor, an x-ray sensor, a cosmic ray sensor, a visible light sensor, a gamma ray sensor, a stress sensor, a strain sensor, a depth sensor, or an electrical characteristic sensor.

The sensor **32** includes a voltage sensor, a current sensor, a viscosity sensor, an acoustical sensor, a sound sensor, a listening sensor, a thickness sensor, a density sensor, a surface quality sensor, a volume sensor, a physical sensor, a mass sensor, a weight sensor, a conductivity sensor, a distance sensor, an orientation sensor, or a vibration sensor.

The sensor **32** can include a radioactivity sensor, a field strength sensor, an electric field sensor or a magnetic field sensor, a smoke detector, a carbon monoxide detector, a radon detector, an air quality sensor, a humidity sensor, a glass breakage sensor, or a break beam detector. The sensor can include a thermal energy sensor, an electromagnetic sensor, a mechanical sensor, an optical sensor, a radiation sensor, a sensor in contact with a vehicle, or a sensor **32** in contact with a water craft.

The present invention pertains to an apparatus **10** for an application. The apparatus **10** comprises a core device **22** having an integrated circuit **36** for the application. The apparatus **10** comprises means for receiving energy wirelessly and providing power from the energy to the core device **22** to power the integrated circuit **36** of the core device **22**. The receiving means is connected to the core device **22**. Preferably, the core device **22** includes means for sensing.

The present invention pertains to a method for an application. The method comprises the steps of converting RF energy into usable energy. There is the step of preferably powering an integrated circuit **36** of the core device **22** with the usable energy.

Preferably, there is the step of regulating the usable energy provided to the core device **22**. There is preferably the step of storing the usable energy. Preferably, there is the step of providing power to the core device **22** from an alternative power source **24** in conjunction with the usable energy.

Alternatively, the core device **22** can include a computer peripheral **34**, as shown in FIG. **90**. The computer peripheral **34** can include a handheld game, a gaming system, a game controller, a controller, a keyboard, a mouse, a computer terminal, computer storage, or computer equipment.

The present invention can be implemented in numerous ways. A number of these ways are depicted in FIGS. **1-90**. These figures contain multiple blocks that are configured in multiple ways.

In the figures, an arrow represents the flow of power unless otherwise stated. Single-headed (one-way) arrows represent that the power is flowing from one block to another. The single-headed arrow may represent multiple wires that provide power from one block to multiple parts in the other block. Two-headed (two-way) arrows represent a single wire that can have power flow in either direction or multiple wires each having power flow in a single direction.

As an example, a two-headed arrow between an RF power harvesting **20** block and a power regulation **26** and/or power storage circuit **28** block can represent a single wire that allows harvested power to flow into a storage device such as a capacitor. The same block diagram can also represent two wires between the two blocks with the first wire allowing harvested power to flow into a voltage regulator **26**. The second wire can allow the regulated voltage to feedback to the RF power harvesting **20** block to provide power to internal components such as transistors to increase the performance of the RF power harvesting **20** block.

Each block is described in detail below. Each block represents the functionality described below associated with it. For instance, the RF power harvesting **20** block describes a power harvester **20**, and the power regulation **26** and/or power storage circuit **28** block describes a power regulator **26** and a power storage circuit **28**.

Device's Power System Block

The device's power system block includes all components/circuitry required to power the device. This block may include an RF power harvesting **20** block, a power regulation **26** and/or power storage circuit **28** block, a power storage block, and/or a power storage charger **30** block (all discussed below).

RF Power Harvesting **20** Block

The RF power harvesting **20** block is connected to an antenna. The antenna may or may not be used as the communications antenna for the core device **22** components. The RF power harvesting **20** block is used to convert the energy captured by the antenna into usable power, such as direct current (DC) voltage.

This block may include antenna matching, rectifying circuitry, voltage transforming circuitry, and/or other performance optimizing circuitry. The rectifying circuitry may include a diode(s), a transistor(s), or some other rectifying device or combination. Examples of the rectifying circuitry include, but are not limited to, half-wave, full-wave, and voltage doubling circuits.

The output of the RF power harvesting **20** block is a DC voltage or current. The RF power harvesting **20** block may accept feedback (or input) from other circuitry or blocks, which may be used to control the harvesting circuitry to improve the performance or vary the output. This feedback may include, but is not limited to, a DC voltage or a clock from the core device **22** components.

U.S. Pat. No. 6,615,074 (FIGS. 8, 9, 12a, 12b, 13, 14), incorporated by reference, herein, shows numerous examples of RF power harvesting circuits that can be used to implement the block and function described.

Power Regulation **26** and/or Power Storage Circuit **28** Block

It may be necessary to regulate the converted power (i.e., hold the power at a constant level) for specific devices. The devices that would need this block require a fairly constant voltage or current. Deviations from the required values may cause the device to not perform within its specifications.

The regulation can be implemented in many different ways. The block can be as simple as using a Zener diode, or as complicated as using an integrated circuit such as a linear voltage regulator **26** or switching regulator **26** to hold the voltage at a constant level.

Certain devices have a more tolerable power requirement. For these devices, the regulation stage may be excluded.

This block may also include, with or without the regulation, a storage device such as a capacitor, a battery, or some other device able to store charge. The output from the power regulation **26** and/or power storage circuit **28** block may be used as feedback to other blocks within the device's power system block or to the alternative power sources **24** block (described below), if they require a regulated supply voltage or stored power.

U.S. Pat. No. 6,894,467 (FIGS. 1, 3), Linear Voltage Regulator, incorporated by reference, herein, is an example of a practical application of implementing the regulation described in the block. U.S. Pat. No. 6,297,618 (FIGS. 1-4), Power storage device and method of measuring voltage of storage battery, incorporated by reference, herein, is an example of a practical application of implementing the storage described in the block.

Power Storage Charger **30** Block

The power storage charger **30** block may be needed if a power storage component of the device requires a special charging mechanism, such as pulse charging or trickle charging. This block controls how the captured and converted power is supplied to the power storage component.

U.S. Pat. No. 6,836,095 (FIGS. 1-3), Battery Charging Method and Apparatus, incorporated by reference herein, is an example of a practical application of implementing the special charging mechanism described in the block.

Power Storage Block

If a device has intermittent power requirements, it may be necessary to store the captured power for use at a later time. The power can be stored in the power storage block, which could include a battery, a capacitor, and/or another type of power storage component. Power storage components include, but are not limited to, batteries (rechargeable and non-rechargeable), capacitors, inductors, fuel cells, and other power storage elements.

The output from the power storage block may be used as feedback to other blocks within the device's power system or to the alternative power sources **24** block, if they require a dedicated and predictable supply voltage.

U.S. Pat. No. 6,297,618 (FIGS. 1-4), Power Storage Device and Method of Measuring Voltage of Storage Battery, incorporated by reference herein, is an example of a practical application of implementing the storage described in the block. U.S. Pat. No. 6,835,501, Alkaline Rechargeable Battery, incorporated by reference herein, is also an example of a practical application of implementing the storage described in the block.

Core Device **22** Components Block

The core device **22** components block is the portion of the device that is receiving power from the device's power system. This block may be, but is not limited to, the devices listed in the subsequent pages of this document. It may be advantageous for the core device **22** components block to communicate with any of the blocks that are supplying power to it. This communication can include, but is not limited to, a feedback control signal such as a clock or an ON/OFF command. As an example, the device may want to turn off the alternative power sources **24** block if it is receiving sufficient power from the RF power harvesting **20** block.

Alternative Power Sources **24** Block

RF energy harvesting also has the ability to be augmented by other types of power harvesting, storage components, or dedicated sources (e.g. power line). The alternative power sources **24** block shows how this type of system could be implemented. The augmenting power harvesting technologies include, but are not limited to, solar, light (visible and non-visible), piezoelectric, vibration, acoustic, thermal, microgenerators, wind, and other environmental elements. This block can work independently or have communication with other blocks.

U.S. Pat. No. 6,784,358, Solar Cell Structure Utilizing an Amorphous Silicon Discrete By-Pass Diode, incorporated by reference herein, is an example of a practical application of implementing an alternative power source **24** described by the block. U.S. Pat. No. 6,858,970, Multi-Frequency Piezoelectric Energy Harvester, incorporated by reference herein, is also an example of a practical application of implementing an alternative power source **24** described by the block.

Power Regulation **26**, Storage **28** and/or Storage Charging **30** Block

The power regulation **26**, storage **28** and/or storage charging **30** block contains all the combinations of the power regulation **26** and/or power storage circuit **28** block, power storage charger **30** block, and power storage block. This block is used in the later figures to reduce the number of figures needed to show how the blocks can interconnect.

The disclosed invention is an apparatus and method for an application for retrieving radio frequency (RF) energy by an antenna, converting that energy into direct current (DC) power, regulating that energy using an optimized circuit, storing that energy in an optimized component, and/or supplying the power for a specific device.

Retrieval of RF Energy

The RF energy is retrieved from the environment by the use of the antenna. The antenna can be shared or standalone with respect to an antenna used for the device's wireless communication. FIGS. **54-56** show a device that has an antenna A for use by the RF power harvester **20** and an antenna B used for wireless one-way or two-way communication. FIGS. **57-59** show a device where the antenna is shared by both a device's communication module (within the core device **22** components) and the RF power harvester **20**. In terms of form factor, the antenna used by the apparatus **10** can be a separate component or integrated directly into the form factor of the device.

The antenna is able to capture two types of available RF energy. The first type of energy exists as ambient RF energy. This type of RF surrounds us in our day-to-day lives and is usually generated to carry one way or two-way combinations of voice, video and data communications. The sources that the antenna can harvest from include, but are not limited to, medium-frequency AM radio broadcast, very-high-frequency (VHF) FM radio broadcast and television broadcast, ultra-high-frequency (UHF) broadcast, cellular base stations, wireless data access points, super-high-frequency (SHF) frequencies, and the industrial, scientific, and medical (ISM) bands. These sources cover transmission frequencies from 300 kHz to 30 GHz.

The second type of energy available is directed RF energy. This type of RF energy is directed from a transmitter specifically designed to deliver RF energy for harvesting by the antenna. The transmitter can be configured as a standalone device or integrated into an existing device.

Conversion of the Energy into DC

The RF energy captured by the antenna must be converted into a useful form of energy for the specific device. This conversion is shown in block form in all FIGS. (**1-90**) as the RF power harvesting **20** block. The most common form of useable energy is DC energy. To perform this conversion, the block includes circuitry to rectify the captured alternating current (AC) energy to create DC energy. The rectification in this block can be done with a diode(s), a transistor(s), or some other rectifying device or combination.

Regulation of the Energy

It may be necessary to regulate the converted power (hold the power at a constant level) for specific devices. FIGS. **2-7**, **10-17**, and **22-53** show how this regulation can be implemented using a power regulation **26** and/or power storage circuit **28** block. The devices that would need this block require a fairly constant voltage or current. Deviations from the required values may cause the device to not perform within its specifications. The regulation can be implemented in many different ways. The block can be as simple as using a Zener diode, or as complicated as using an integrated circuit such as a linear voltage regulator **26** or a switching regulator **26** to hold the voltage at a constant level. Certain devices have a more tolerable power requirement. For these devices, the regulation stage may be excluded.

Storage of the Energy

If a device has intermittent power requirements, such as the devices exampled by FIGS. **2-53**, it may be necessary to store the captured power for use at a later time. The power can be stored in the power storage block or the power regulation **26** and/or power storage circuit **28** block. Storage devices can include, but are not limited to, a battery, a capacitor, or another type of power storage component. In certain applications, it may be necessary to include additional circuitry that controls how the power is transferred to the storage device. The power storage charger **30** block is shown in FIGS. **18-53**. This may be needed if the power storage component requires a special charging mechanism such as pulse charging or trickle charging. Power storage components include, but are not limited to, batteries (rechargeable and non-rechargeable), capacitors, inductors, fuel cells, and other storage elements. There are devices that will not require storage. These devices can run directly off of the converted power. These devices also may or may not require regulation of the captured power.

Supplying the Power

The captured DC power, which may or may not be regulated and/or stored, is supplied to the device, which is represented by the core device **22** components block in the figures. This may be a single connection or it may supply multiple parts of the device with power.

RF energy harvesting also has the ability to be augmented by other types of power harvesting or storage components. Other power harvesting technologies include, but are not limited to, solar, light (visible and non-visible), piezoelectric, vibration, acoustic, thermal, microgenerators, wind, and other environmental elements. Power storage components include, but are not limited to, batteries (rechargeable and non-rechargeable), capacitors, inductors, fuel cells, and other storage elements. FIGS. **60-88** show how the alternative power sources **24** block can be connected to an RF energy harvesting system. These figure show how the RF energy harvesting **20** block and the alternative power sources **24** block can work independently or have communication with each other. The antenna configurations shown in FIGS. **54-59** are still applicable with the addition of an alternative power sources **24** block. These antenna configurations can be applied to FIGS. **60-88**.

RF energy harvesting also has the ability to provide a backup to devices on-grid (tethered) or with reliable power sources, which can be used in case the primary power source is lost. As an example, it may be mandated by regulations that a sensor has auxiliary power in case the primary supply is lost. It could be possible to use a rechargeable battery that obtains its charge from the primary supply when in operation. However, if the primary supply is lost for a time greater than the life of the rechargeable battery, the specification of uninterrupted power is not met. RF energy could be used to supply power to the described device while the primary supply is not available. The primary supply could include, but is not limited to, an on-grid connection, a generator, a battery, or other reliable power supply.

RF energy harvesting with or without alternative source augmentation is applicable to provide electric power directly or indirectly to a range of electronic components contained in any specific electrical or electronic device and includes, but is not limited to:

Passive electronic components, active electronic components;

Resistors, fixed resistors, variable resistors, thermistors, thyristor, thermocouple;

Capacitors, Electrolytic Capacitors, Tantalum Capacitors, Ceramic Capacitors, Multilayer Ceramic Capacitors, Polystyrene Film Capacitors, Electric Double Layer Capacitors (Super Capacitors), Polyester Film Capacitors, Polypropylene Capacitors, Mica Capacitors, Metallized Polyester Film Capacitors, Variable Capacitors;

Diodes, Voltage regulation diodes, light-emitting diodes, organic light-emitting diodes, Variable capacitance diodes, Rectification diodes, Switching diodes, Regulation Diodes, Diode bridges, Schottky barrier diodes, tunnel diodes, PIN diodes, Zener diodes, Avalanche diodes, TVSs;

Integrated circuits, microcontroller unit (MCU), microprocessor unit (MPU), logic circuits, memory, printed circuits, circuit boards, printed wiring boards;

Transistors, MOSFETs, FETs, BJTs, JFETs, IGBTs, Relays, Antennas, semiconductors, conductors, inductors, relays, diacs, triacs, SCRs, MOVs;

Fuses, circuit breakers;

Batteries, Non-rechargeable batteries, rechargeable batteries, coin cell batteries, button cell batteries, alkaline batteries, lithium batteries, lithium ion batteries, lithium polymer batteries, NIMH batteries, NICAD batteries, Lead acid batteries, Zinc air batteries, Manganese Lithium batteries, Niobium Titanium Lithium batteries, Vanadium Pentoxide Lithium batteries, Carbon Zinc batteries, Zinc Chloride batteries, Lithium Thionyl Chloride batteries, Manganese Dioxide batteries, Lithium Poly-Carbonmonofluoride batteries, Lithium Manganese Dioxide batteries, Lithium Chloride batteries, Lead Acid Calcium batteries, Lead Acid Tin batteries, Oxy Nickel batteries, Silver Oxide batteries, Magnesium batteries;

Inductors, Coils, High Frequency Coils, Toroidal Coils, Transformers, switches, chokes;

Motors, DC motors, stepper motor, AC motors, Fans;

Crystals, Oscillators, Clocks, Timers; and

Displays, LCDs, LED displays.

RF energy harvesting with or without alternative source augmentation is applicable across a range of markets and specific devices and includes but is not limited to:

Consumer Electronics:

Electronic equipment, wired devices, battery powered devices, wireless communication devices, cell phones, telephones, phones, cordless phones, portable phones, Bluetooth devices, Bluetooth headsets, hands-free headsets, headsets, headphones, Wireless headsets, radios, AM/FM radios, shortwave radios, weather radios, Two-way radios, portable radio, lights, lanterns, portable lights, flashlights, nightlights, spotlights, search lights, calculators, graphing calculators, desk calculators, clocks, alarm clocks, wall clocks, desk clocks, travel clocks, watches, wristwatches, pocket watches, stop watches, timers, voice recorders, Dictaphones, laser pointers, power tools, cordless power tools, electronic razors, electric razors, handheld games, gaming systems, game controllers, wireless game controllers, remote controls, battery chargers, computers, portable computers, keyless entry, toys, toy guns, toy laser guns, games, microphones, musical instruments, musical effects processors, musical instrument tuners, metronomes, electronic chord charts, door openers, garage door openers, PDA, Cameras, Video recorders, Multimeter, electronic test equipment, hand-held electronics, portable electronics, wireless pens, sound generators, noise generators, language translators, electric toothbrushes, portable televisions, pagers, transceivers, toy vehicles, remote control vehicles, toy planes, remote control planes, pet containment systems, invisible fence pet sensors, memory backup, base station battery backups, appliance battery backups, uninterrupted power supplies, GPS devices, memory retention power supplies, metal detectors, stud finders, metal stud finders, stun guns, tazers, wearable devices, baby monitors, intercoms, doorbells, wireless doorbells, electronic office supplies, electronic staplers, radar jammers, radar detectors, digital scales, microfilm cassettes, video head testers, compasses, noise canceling headphones, air samplers, depth finders, barometers, weather measurement instruments, data transfer devices, automatic distress signaling unit, Wireless audio speakers, Satellite radios, Police scanners, Car navigation systems (GPS devices), Decorative lights, Christmas lights, garden lights, lawn lights, ornamental lights, porch lights;

Multi-media players: MP3, DVD, analog music players, CD players, tape players, digital music players, digital video players, minidisc; and

Computer: keyboards, mice, peripherals, computer equipment, electronic computers, computer storage, computer terminals;

Building/Industrial Automation:

Sensors: Position, elevator, temperature, fire, accelerometers, level, gas level, fluid level, light level, flow, gas flow, fluid flow, light flow, plasma flow, pressure, gas pressure, fluid pressure, motion, light, infrared light, ultraviolet light, X-rays, cosmic rays, visible light, gamma rays, chemical, stress, strain, depth, electrical characteristics, voltage, current, viscosity, acoustical, sound, listening, thickness, density, surface quality, volume, physical, mass, weight, force, conductivity, distance, orientation, vibration, radioactivity, field strength, electric field strength, magnetic field strength, occupancy, smoke detector, carbon monoxide detector, radon detector, air quality, humidity, glass breakage, break beam detector;

Controls: Position, elevator, temperature, fire, accelerometers, level, gas level, fluid level, light level, flow, gas flow, fluid flow, light flow, plasma flow, pressure, gas pressure, fluid pressure, motion, light, infrared light, ultraviolet light, X-rays, cosmic rays, visible light, gamma rays, chemical, stress, strain, depth, electrical characteristics, voltage, current, viscosity, acoustical, sound, listening, thickness, density, surface quality, volume, physical, mass, weight, force, conductivity, distance, orientation, vibration, radioactivity, field strength, electric field strength, magnetic field strength, occupancy, smoke detector, carbon monoxide detector, radon detector, air quality, humidity; and

Devices: Thermostats, light switches, door locks, smart-card door locks, lighting, emergency lighting, motion lighting, safety lighting, highway lighting, construction lighting, sign lighting, roadway sign lighting, construction sign lighting, automatic flushing units, automatic soap dispenser, automatic paper towel dispenser, automatic faucets, automatic door sensors, identification reader, fingerprint reader, credit card readers, card readers, valve actuators, gauges, analog gauges, digital gauges, fire extinguishers, wireless switches, remotely operated inspection equipment, gas/oil pipeline monitoring systems, robotic pipeline inspection gauges, “auto-reclosers” for electric power lines, sonar buoys, telemetry systems, electronic record tracking systems, robbery tracking devices, interrogators, programmers, emergency exit alarms, alarms, flood alarms, gas alarms, electronic entry systems, security keypads, silo transducers, data recorders, signal tracers, anti-static strap testers, radiosonde weather balloons, utilities load controllers, profilometers, noise cancellation equipment, infrared beacons;

Military/Government:

Tracking tags: Weapons, vehicle, soldier, gear/assets, staff, general population, security access badges;

Sensors: Proximity, intrusion, environmental, chemical/biological; and

Equipment: Battery charger, surveillance, card readers, identification reader, fingerprint reader, retinal scanners, satellites, rockets, space vehicles, search and rescue transponders (SARTs), emergency position-indicating rescue beacons (EPIRBs), emergency locator transmitters (ELTs), military radios, electronic toll collection systems, postal tracking systems, communications, thermal imaging, night vision, training targets, field medical equipment, house arrest monitors, laser tags, electronic parking meters, multiple integrated laser engagement system, munitions and mines, ship sensors;

Utility:

Gas consumption meters, water consumption meters, and electric consumption meters;

Logistics & Supply Chain Management:

Radio-frequency identification devices (RFID), RFID readers;

Tracking: Asset tags, cargo container location beacons, transponders, transceivers; and

Devices: Smart price tags, smart shelving, handheld barcode scanner, barcode scanners, credit card readers, card readers, retail signage, hotel door locks;

Homeland Security:

Sensors: Occupancy, proximity, environmental, chemical/biological, motion, position; and

Metal detector wand;

Medical:

Implantable: cochlear implants, neural stimulators, pace makers, medication administration, defibrillator;

Body function monitors: pressure, temperature, respiration, blood oxygenation, insulin, hearing aid, pulse, EKG, heart, Holter;

Tracking tags: Patient, baby identification, assets, supplies, staff, medication, instruments;

Devices: Home healthcare equipment, ambulatory infusion pumps, blood analyzers, biofeedback systems, bone growth stimulators, thermometers, digital thermometers, stimulators, galvanic stimulators, muscle stimulators, pediatric scales; and

Agriculture—Livestock Tracking and Asset Tracking:

Tracking: livestock, asset, wildlife tracking devices; and

Equipment: cattle prods;

Automotive:

Automotive antennas, Automotive Audio Systems, Automotive Lighting, Automotive Video Systems, Computers, Processors, Controls, Switches, Electric Motors, Actuators, Ignition Systems, Starter Systems, Injection Systems, Powertrain Electronics, Radar Detectors, Proximity Detectors, Safety Systems, Security Systems, Sensors, Regulators, Distributors, Vehicle Control, Wiper Systems, Washer Systems, Radio, Video Systems, Entertainment Systems, Navigation Systems, GPS systems, Power Mirror Systems, Emission control systems;

Appliances:

Monitoring systems and control systems for major and small appliances including washing machines, dryers, refrigerators, freezers, coolers, air conditioners, humidifiers, dehumidifiers, air purifiers, air filters, fans, furnaces, water heaters, boilers, space heaters, sowing machines, ice makers, microwave ovens, convection ovens, ovens, toaster ovens, ranges, range hoods, cooktops, stoves, stovetops, crock pots, hot plates, dishwashers, garbage disposals, can openers, vacuum cleaners, blenders, mixers, food processors, irons, coffee makers, toasters, grills, hair dryers, electric tooth brushes, electric razors, electric drills, electric screwdrivers, chainsaws, lawnmowers, push mowers, riding mowers, trimmers, brush cutters, pruners, edgers, vending machines;

Ventilation, Heating, Air-Conditioning, and Commercial Refrigeration Equipment:

Monitoring systems, control systems;

Engine, Turbine, and Power Transmission Equipment;

Monitoring systems, control systems;

Other General Purpose Machinery Manufacturing:

Monitoring systems, control systems;

Telecommunications:

Monitoring systems, control systems;

Portable;

Aircraft:

Monitoring systems, control systems, actuator systems, sensors.

It should be noted that devices within a specific category may be applicable across multiple areas even if they are not specifically listed. (e.g., temperature sensors apply to Industrial and Building Automation and Appliances).

To retrofit or redesign the devices listed, it is possible to implement the described systems in numerous ways. It may be advantageous to leave the device design as-is including the existing power supply. As an example, a device may use non-rechargeable batteries to operate. The device will most likely have a protection circuit to prevent damage if the batteries are installed incorrectly. The protection mechanism is commonly a diode inline with the positive terminal of the battery. In this case, the RF power harvester **20** with or without the alternative power source **24** could be inserted, with an antenna, into the device. The power generated by the RF power harvester **20** (and the alternative power source **24**, if applicable) could be connected to the device after the protection mechanism described to avoid potential charging of a non-rechargeable battery.

Another way to configure the device's power system is to replace the non-rechargeable batteries with rechargeable batteries. In this instance, the output from the RF power harvester **20** (and alternative power source **24**) could be connected to either side of the protections device. If the connection is before the protection mechanism, the RF power harvester **20** (and the alternative power source **24**, if applicable) will recharge the battery and supply power to the device. If the connection is after the protection mechanism, the RF power harvester **20** (and the alternative power source **24**, if applicable) will supply power to the device and the battery will supply any extra power needed that could not be supplied by the RF power harvester **20** (and the alternative power source **24**, if applicable). It should be noted that the protection device in this case is not needed for proper operation. Its only function would be to protect the batteries from being installed incorrectly. An antenna could be contained inside or placed on the outside of the device.

Another configuration of the device's power system is to remove the existing batteries and install the RF power harvester **20** (and the alternative power source **24**) in the enclosure provided for the batteries. An antenna could be contained inside or placed on the outside of the device.

Yet another method of configuring the device's power system would be to reduce the number of batteries and replace them with the RF power harvester **20** (and the alternative power source **24**). In this case, the output from the system would be connected to the batteries in series or parallel depending on the original battery configuration. An antenna could be contained inside or placed on the outside of the device.

An additional option, would be to completely redesign the product and integrate the required circuitry and storage components into the device. This method is probably the most advantageous because it can fully take advantage of the benefits offered by the RF power harvester **20** (and the alternative power source **24**). An antenna could be contained inside or placed on the outside of the device.

If the RF power harvester **20** (and the alternative power source **24**) is used as a backup to the primary power supply, a switch could be implemented into the system in order to switch the RF power harvester **20** (and the alternative power source **24**) on when the primary source is lost. In this case, an antenna could be contained inside or placed on the outside of the device.

To show the flexibility of RF energy harvesting, several products were retrofitted to include an RF power harvester **20** (energy harvesting circuitry). These products include a wireless keyboard, a wall clock, and a desk calculator.

The wireless keyboard is an example of recharging and augmenting a battery to supply power to a device. This system is shown in FIG. **13**. The output from the regulation circuitry recharges the battery and supplies power to the keyboard. The battery is also used to supply power to the keyboard. The keyboard also includes a separate antenna for receiving power and for data communications. The antenna configuration can be seen in FIG. **55**.

The wall clock is an example of a direct powering system. The wall clock was retrofitted to include an RF power harvester **20** and the internal AA battery was removed. This system is shown in FIG. **2**. The wall clock did not need regulation, but did require a capacitor for storage to supply the pulse of power to move the second hand.

The calculator is an example of using RF energy harvesting with another energy harvesting technology. The calculator had an internal 1.5V coin cell battery and a small solar panel. The internal battery was removed, however, the solar panel was left intact. This system is shown in FIG. **60**. In this system, the calculator can receive power from both the solar panel and the RF power harvester **20** to eliminate the need for a battery.

As an additional example, an RF power harvester **20** (energy harvesting circuit) similar to the ones shown in U.S. Pat. No. 6,615,074 (FIGS. 8, 9, 12a, 12b, 13, 14), was connected in series with a 0.5V solar cell. Individually, the solar cell was able to provide 0.480V to a 10 kilo-ohm resistor, which was being used to simulate the core device **22** components. This corresponds to 23 microwatts. The RF power harvesting circuit by itself was able to provide 2.093V across the 10 kilo-ohm resistor when being supplied by 1 milliwatt of RF power. This corresponds to 438 microwatts. The two circuit outputs were then combined in series by connecting the output from the RF energy harvesting circuit to the ground of the solar cell. The output of the solar cell was then connected to the resistor. The other end of the resistor was connected to the ground of the RF energy harvesting circuit. The voltage across the resistor with the circuits connected as shown in FIG. **63** was 2.445V. This corresponds to 598 microwatts.

As can be seen, the combination of the two technologies produces a result higher than the addition of the individual powers. From this, it can be determined that the two technologies can cooperate in a way that produces favorable results.

In the example given, the solar cell produces current to supply the load and helps to bias the RF rectifying diodes, which allows the RF energy harvesting circuit to operate a higher efficiency. The solar cell also changes the impedance seen by the RF energy harvesting circuit, which produces a beneficial result. To be more specific, when examining the power output of the individual circuit (solar and RF power harvesting), the sum of the power captured by the individual circuits was 23 μW+438 μW=461 μW. However, when the two circuits are combined and are allowed to work in conjunction with one another, the output power becomes 598 μW. This result shows that combining the two power-harvesting technologies produces a 30 percent increase in the output power for this example. This same technique can be applied to multiple energy harvesting technologies to produce even greater output power. The equations for this example are shown below.

Individual Circuits

$$P_I=P_1+P_2+\ldots+P_N$$

Combined Circuits

$$P_C>P_I=P_1+P_2+\ldots+P_N$$

where P_I is the sum of the individual output powers

P_C is the output of the combined circuit

P_1 is the output power from the first power harvesting technology

P_2 is the output power from the second power harvesting technology

P_N is the output power from the N^{th} power harvesting technology

N is the number of power harvesting technologies or circuits.

As can be seen by the previous examples, RF energy harvesting can be used alone or in conjunction with alternative power sources to power a wide range of devices. The addition of RF energy harvesting technology to the device allows for increased battery life, increased functionality, or the removal of the primary battery.

Although the invention has been described in detail in the foregoing embodiments for the purpose of illustration, it is to be understood that such detail is solely for that purpose and that variations can be made therein by those skilled in the art without departing from the spirit and scope of the invention except as it may be described by the following claims.

The invention claimed is:

1. An apparatus, comprising:

a power harvester configured to convert energy received via an antenna to a DC voltage;

a power storage device configured to store a power associated with the DC voltage;

a power storage charger operatively coupled to the power harvester, the power harvester configured to provide an activation signal to the power storage charger to trigger storage of the power associated with the DC voltage at the power storage device;

a sensor configured to operate based on the DC voltage, the sensor configured to detect an environmental condition associated with a location of the sensor; and

an integrated circuit configured to operate based on the DC voltage, the integrated circuit configured to perform an application associated with the environmental condition detected by the sensor.

2. The apparatus of claim **1**, wherein:

the DC voltage is a first DC voltage, the integrated circuit is configured to operate based on the first DC voltage or a second DC voltage from a power source.

3. The apparatus of claim **1**, wherein:

the power associated with the DC voltage is a first power associated with the DC voltage; and

the integrated circuit is configured to produce a control signal that causes a second power associated with the DC voltage to be transferred from the power harvester to the integrated circuit.

4. The apparatus of claim **1**, wherein:

the sensor and the integrated circuit are each configured to operate based on the power associated with the DC voltage stored in the power storage device; and

the power harvester is configured to be disabled when the power associated with the DC voltage stored in the power storage device is sufficient for at least one of the sensor or the integrated circuit to operate.

5. The apparatus of claim **1**, wherein:

the power storage charger configured to control storage of the power associated with the DC voltage at the power storage device, the power storage charger configured to operate in a power pulse charging mode.

6. The apparatus of claim **1**, wherein:

the power storage charger configured to control storage of the power associated with the DC voltage at the power storage device, the power storage charger configured to operate in a power pulse charging mode or a power trickle charging mode.

7. The apparatus of claim **1**, wherein:

the power harvester is configured to receive at least one of an ambient radio frequency energy, a directed radio frequency energy, or an energy from a power source connected to the power harvester.

8. The apparatus of claim **1**, wherein:

the integrated circuit is configured to provide a deactivation signal to a power source when the power associated with the DC voltage is more than a predetermined power value, the deactivation signal configured to impede output of a power from the power source, the power source different from the power harvester and the power storage device.

9. The apparatus of claim **1**, wherein the power storage device is a first power storage device, the apparatus further comprising:

a second power storage device operatively coupled to the first power storage device and the integrated circuit, the second power storage device configured to store a portion of the power associated with the DC voltage and provide the portion of the power associated with the DC voltage to at least one of the sensor or the integrated circuit.

10. The apparatus of claim **1**, wherein the apparatus is part of a radio-frequency identification tag.

11. The apparatus of claim **1**, further comprising:

a display configured to operate, at least in part, based on the DC voltage.

12. The apparatus of claim **1**, wherein the sensor is at least one of a temperature sensor, a humidity sensor, a stress sensor, a strain sensor, a vibration sensor, an accelerometer, a level sensor, or a light sensor.

13. An apparatus, comprising:

a power harvester configured to convert energy received via an antenna to a DC voltage to produce a power associated with the DC voltage;

a regulator coupled to the power harvester and configured to regulate the power associated with the DC voltage, the regulator configured to transfer the regulated power to a power storage charger of the apparatus;

a power storage device configured to store power;

the power storage charger coupled to the power harvester and the regulator, the power storage charger configured to control the storage of the regulated power associated with the DC voltage to the power storage device; and

an integrated circuit configured to operate based on the power received from the power harvester or from the power storage device,

the power harvester configured to transfer power associated with the DC voltage to the regulator, the power harvester configured to transfer power associated with the DC voltage to the power storage device, the power harvester configured to transfer power associated with the DC voltage to the integrated circuit.

14. The apparatus of claim **13**, wherein:

the power storage charger is configured to operate in a power pulse charging mode or a power trickle charging mode.

15. The apparatus of claim **13**, further comprising:

a sensor configured to operate based on the power received from the power harvester or from the power storage device, the sensor configured to detect an environmental condition associated with a location of the sensor or a physical condition associated with an item coupled to the sensor, the integrated circuit configured to perform an application associated with the environmental condition or the physical condition detected by the sensor.

16. The apparatus of claim **13**, wherein:

the regulator is configured to send a control signal that causes the power harvester to vary an amount of the power associated with the DC voltage transferred from the power harvester to the regulator.

17. The apparatus of claim **13**, wherein:

the power storage device is configured to send a control signal that causes the power harvester to vary an amount of the power associated with the DC voltage transferred from the power harvester to the power storage device.

18. The apparatus of claim **13**, wherein the apparatus is part of a radio-frequency identification tag.

19. The apparatus of claim **13**, wherein the integrated circuit is in communication with a sensor configured to detect an environmental condition associated with a location of the sensor, the sensor being at least one of a temperature sensor, a humidity sensor, a stress sensor, a strain sensor, a vibration sensor, an accelerometer, a level sensor, or a light sensor.

20. The apparatus of claim **13**, further comprising:

a display configured to operate, at least in part, based on the DC voltage.

(57) ABSTRACT

Provided is an RF power harvesting circuit with improved sensitivity to RF energy. The RF power harvesting device includes an inductor, a first capacitor connected to the inductor, a first MOSFET connected to a first node, and a second MOSFET connected to the first node. The inductor or the first capacitor are connected to the first node.

RF POWER HARVESTING CIRCUIT

CROSS-REFERENCE TO RELATED PATENT APPLICATION

[0001] This application claims priority from U.S. Provisional Application No. 61/118,808 filed on Dec. 1, 2008, and U.S. Provisional Application No. 61/119,848 filed on Dec. 4, 2008, the disclosures of which are incorporated herein by reference in their entirety.

STATEMENT REGARDING FEDERALLY SPONSORED R&D

[0002] This invention was made with support under H9823004C0490 awarded by the National Security Agency. The government has certain rights in the invention.

BACKGROUND

[0003] 1. Technical Field

[0004] The present invention relates to an RF power harvesting circuit design, and more particularly, to an RF power harvesting circuit design which efficiently harvests power from RF energy.

[0005] 2. Description of the Related Art

[0006] Electronic devices are ubiquitous throughout the world today, with immeasurable applications and devices permeating all aspects of society. Energy that would have been wasted by such devices can now be recycled. For example, in some related art electronic devices (e.g., a mobile device) that generate radio frequency (RF), the RF is harvested back into the electronic device. All electronic devices require power to operate. Ambient energy in any form is an attractive source of power, particularly as power becomes more costly, or in areas where it is scarce. Ambient energy is also desirable where there is a need for electronic devices to operate for longer times between connection to readily available sources of power, or when there is a need to remotely recharge electronic devices, or to improve the overall efficiency of electronic devices. Of course, instead of scavenging for the ambient RF energy, intentional beaming of RF energy to a target device is also possible.

[0007] In this context, radio frequency (RF) energy represents an attractive source of power. Many electronic devices (e.g., communications devices) emit RF energy. For example, indoor power densities greater than 0.5 uW/cm^2 can be detected even a kilometer away from an FM radio tower. Comparable power densities can be detected at higher frequencies both domestically and internationally including GSM and ISM bands. Harvesting this energy from the environment can provide many benefits to electronic circuit and device designers. These benefits include, but are not limited to, extending operational life of electronic devices, providing new benefits such as remote recharging, reducing size of the electronic devices, and improving overall device efficiency.

[0008] RF power harvesting devices/RF energy scavenging devices have been constructed to capture this energy. An example of a related art power harvesting circuit is shown in FIG. **1**. FIG. **1** illustrates the basic Villard voltage doubler circuit. An intuitive understanding of this circuit can be gained by first examining what occurs when current flows in the direction of I_1. The diode D_2 blocks the flow of current through the capacitor C_2.

[0009] Therefore, all of the current goes across the capacitor C_1. This charges the capacitor C_1 up to roughly the same level as the peak of the AC voltage. Once the up-swing of the AC cycle (I_2) has been reached, the diode D_1 turns off, the diode D_2 turns on, and the voltage across both the AC source and C_1 drops across the capacitor C_2, charging it to approximately twice the peak voltage of the AC signal.

[0010] The related art RF scavenging circuits, however, require a minimum or threshold amount of incident RF energy to "turn on" and begin providing useful energy to other circuits and devices. Such devices can be devices that immediately perform a function or energy storage devices such as batteries and capacitors. Incident energy that falls below the minimum threshold is not captured, thereby reducing the efficiency and effectiveness of the scavenging circuit. Thus, there is a need for an RF power harvesting device that can capture and utilize ambient energy that falls below the minimum threshold for turning on the device.

SUMMARY

[0011] Embodiments of the disclosed RF energy harvesting circuit improve the sensitivity of RF energy harvesting circuits over the related art power harvesting circuits.

[0012] According to an aspect of the present invention, there is provided an RF power harvesting device including an inductor, a first capacitor connected to the inductor, a first MOSFET connected to a first node, and a second MOSFET connected to the first node, and the inductor or the first capacitor are connected to the first node.

[0013] In the RF power harvesting device, values of the first MOSFET and the second MOSFET are such that intrinsic capacitances of the first MOSFET and the second MOSFET and the inductor constitute a substantially resonant circuit during operation of the RF power harvesting device.

[0014] The RF power harvesting device of claim **1** further includes a second capacitor connected to a second node, and the second MOSFET is connected to the second node, wherein the second MOSFET is a PMOSFET.

[0015] The RF power harvesting device further includes a receiver which detects and receives ambient RF energy, and the first capacitor and the receiver are connected at a third node, the first capacitor and the inductor are connected in series at a fourth node, and the inductor is connected to the first node.

[0016] The RF power harvesting device further includes a first set of resisting elements connected to a first gate of the first MOSFET to apply a first DC bias to the first gate, and a second set of resisting elements connected to a second gate of the second MOSFET to apply a second DC bias to the second gate.

BRIEF DESCRIPTION OF THE DRAWINGS

[0017] The above and other features and advantages of the present invention will become more apparent by describing in detail exemplary embodiments thereof with reference to the attached drawings in which:

DETAILED DESCRIPTION OF EXEMPLARY EMBODIMENTS

[0039] The present invention will now be described more fully with reference to the accompanying drawings, in which exemplary embodiments of the invention are shown.

[0040] One embodiment of the present invention provides a modified power matched Villard voltage doubler circuit, compatible with modern complementary metal-oxide-semiconductor (CMOS) processes, which demonstrates the ability to harvest RF electromagnetic energy that is available at power levels as low as in the microwatt range. Revisions to the Villard voltage doubler have been made and accessory circuitry has been added to provide it with the ability to harvest energy from power levels as extremely low as tens of μWatts (micro) low power levels. In the related art, relatively large values of input power of hundreds of μWatts or even higher are required to utilize a Villard voltage doubler topology. The reason for this it that the general Villard voltage doubler topology utilizes rectifying diodes which need to be turned on in order to transform AC currents and voltages into DC currents and voltages, so that their intrinsic energy can be stored. However, turning on these diodes requires several tenths of a volt, and a relatively large amount of input power is typically required to generate these voltages.

[0041] The present invention provides several modifications to the Villard voltage doubler topology, which modifications allow it to harvest energy from very low power levels and go beyond the limitation previously set by the threshold level of the rectifying diodes. For instance, one embodiment of the present invention provides resonant reactive elements are incorporated in a CMOS circuit that allows for the generation of relatively large voltages, without the need for large power, in order to turn on the rectifying diodes. The Villard circuit topology is implemented in an actual CMOS process making it realizable for fabrication as an integrated circuit in modern technology. Certain parasitic elements of the CMOS process are utilized to increase voltage levels and improve circuit performance (typically, parasitic elements limit circuit performance).

[0042] Application specific circuit layout designs are disclosed so that the effect of other parasitic elements would be minimized. Diode connected CMOS devices are used instead of standard diodes to implement the Villard topology. Furthermore, in one embodiment, instead of using an n-type metal-oxide-semiconductor field-effect transistor (NMOSFET), one of the diode functions is implemented using a p-type MOSFET (PMOSFET) polarity. This embodiment mostly eliminates the body effect and allows for the diode connected MOSFETs to be turned on at a lower voltage, thereby giving rise to a lower threshold power in order to obtain AC to DC conversion and allow for energy storage at lower power levels. In another embodiment, a set of sacrificial bias resistors is used to increase the gate voltage of the MOSFETs, and thereby turn them on at a lower voltage which allows for further sensitivity and increases energy harvesting. In addition, in yet another embodiment, circuit blocks are stacked in series to generate even high DC voltage levels from microwatt levels of electromagnetic RF energy.

[0043] It is desirable to integrate the power harvesting circuits of the disclosed embodiments onto CMOS integrated circuits. To accomplish this, the diodes can be replaced with diode connected MOSFETS M**1** and M**2**, as illustrated in FIG. **2**. This modification has an advantage in that it can be naturally fabricated using a CMOS process. Furthermore, using diode connected MOSFETs gives added flexibility for establishing an adjustable effective diode turn on voltage.

[0044] An inductor L**1** can be added near the input power source (RF source) as shown in FIG. **2**. This helps give rise to a matching circuit. In addition to the standard concept of matching, which allows for maximum power transfer from a fixed source impedance, the inductor works in concert with the parasitic intrinsic capacitances usually associated with a MOSFET gate to generate a very large voltage across the reactive components (discussed below in further detail). The generation of such a large voltage is one advantage of using the power harvesting circuit shown in FIG. **1**. Specifically, the generation of the large voltage facilitates the turning on of the CMOS diode connected devices at low incident power levels in order to achieve efficient AC to DC conversion, and ultimately energy storage. Thus, instead of the parasitic intrinsic capacitances functioning to reduce the frequency response and be detrimental to CMOS circuit performance, their reactive nature when working in concordance with the added input inductor L**1** allows for generation of large voltages which will ultimately make the power harvesting device more sensitive to harvesting RF energy. This circuit has a complex impedance that mainly consists mainly of a reactive part.

[0045] A. Modification to Matching Inductor and use of Intrinsic Capacitance for Large Voltage Generation and Diode Turn-On.

[0046] As mentioned previously, in order to be able to utilize the Villard voltage doubler topology, it is necessary to achieve voltages sufficiently large to turn on the diodes (or diode connected MOSFETs) D**1** and D**2**. However, this is difficult if the power of the input signal is very low, in the microwatt range, for example. To overcome this problem, reactive components are utilized in the design which are able to accumulate relatively large amounts of AC power over time, and thus generate voltages that are sufficiently large to turn on the diodes, and thus harvest RF energy even at power levels as low as microwatts.

[0047] The reactive elements that generate the large voltages for turn on are shown in FIG. **3** (e.g., the inductor L**1**, and the intrinsic MOSFET capacitors C_{GS1}, C_{SB1}, C_{GS2}, and C_{SB2}). The inductor L**1** is used to resonate with the capacitive structures intrinsic to the MOSFETs themselves and the fabrication process. The inductor L**1** is an accessory element constructed on the chip. However, instead of adding an accessory capacitor network to generate the complementary reactive impedance, the capacitors that are typically deemed as parasitic and detrimental to circuit performance are utilized in the current embodiment. More specifically, the intrinsic source-gate capacitance (C_{GS1}, C_{GS2}), and the source-body capacitance (C_{SB1}, C_{SB2}) associated with the two diode connected MOSFETS (M**1** and M**2**), are used.

[0048] From FIG. **3**, it can be seen that that accessory inductor L**1** and the intrinsic capacitors C_{GS1}, C_{SB1}, C_{GS2}, and C_{SB2} together form a series resonant circuit. The values of these intrinsic capacitors are in the Femto-Farad range. Furthermore, the capacitors C**1** and C**2** are orders of magnitude larger than the aforementioned CMOS intrinsic capacitors, and thus have negligible impedance at the frequencies of interest (hundreds of MHz to GHz). As such, impedances of the capacitors C**1** and C**1** can be neglected. Considering the relative magnitudes of the intrinsic capacitors with respect to C**1** and C**2**, the intrinsic capacitors can be considered to be at AC ground. Since this is the case, the intrinsic capacitors are in parallel with the gate-source junction of the diode connected MOSFETs. Thus, when large voltages are generated across the capacitive reactive elements, large voltages are also generated across the gate-source voltages (V_{GS}) of the MOSFETs, thereby turning them on and allowing them to operate as rectifiers.

[0049] The optimal response of the circuit is obtained at an input frequency where the accessory matching circuit (comprising of L**1** and the intrinsic capacitors) is in resonance. This condition maximizes the voltage at the input (point B in FIG. **3**) of the circuit, and matches the source impedance of an attached antenna (or any power source) to the complex conjugate of the input impedance of the circuit. Assuming the input power source (i.e., the RF source) has a real source impedance, it can be derived that as long as the following expression (1) is true then the voltage at the input is maximized when the complex impedance (Z_{load}) at the input is matched to the source impedance Rs in FIG. **3** (Rsource in expression 1).

$$\sqrt{\frac{|Z_{load}|}{R_{source}\cos(\phi)}} > 2 \tag{1}$$

[0050] In expression 1, ϕ is the phase difference between the voltage and current wave form. This is equivalent to the phase difference between the real and imaginary components of the load impedance.

[0051] While achieving resonance is optimal for performance, the power harvesting circuit also performs well even when not at resonance. This is because, even at frequencies that are as much as 20% away from resonance, large voltages are still generated across the reactive components, specifically the intrinsic capacitors. These voltages are also in parallel with the gate-source voltage (V_{GS}) of the diode connected MOSFETs, thereby turning them on and allowing for energy harvesting even at power levels in the microwatt range.

[0052] B. Performance Improvement with Parasitic Aware Circuit Layout

[0053] While a schematic diagram of an electronic circuit is an abstraction, once that circuit is constructed into a silicon chip the performance of the current changes. One reason for this is that the physical implementation of passive structures, including inductors, capacitors and interconnects, gives rise to unintentional or parasitic elements. For example, laying out of an on-chip inductor gives rise to unintentional capacitors from the inductor to the substrate ground.

[0054] In one embodiment of the disclosed power harvesting device, performance enhancement can be achieved by switching the order of the impedance matching inductor L**1** and the DC blocking capacitor C**1**, as illustrated in FIG. **4*b***. While theoretically the schematic shown in FIG. **3** is independent of the order of the L**1**-C**1** pair, it becomes apparent after examination of the parasitics incurred during layout, that the schematics in FIG. **3** (also see FIGS. **4*a***) and **4*b*** are different. The schematic produced by the layout shown in FIG. **4*b*** is less sensitive to the negative parasitics associated with the capacitor C**1**.

[0055] In particular, the impedance to voltage doubler at point A in FIG. **3** is dominated by the intrinsic capacitances of the diode connected MOSFETs (C_{GS1}, C_{SB1}, C_{GS2} and C_{SB2}). Therefore, it appears as a short at the RF frequency and the impedance at point B is also highly reactive. The parasitic capacitance of C**1** results in an imaginary impedance parallel to the input impedance at point A and B. This imaginary impedance serves to reduce the magnitude of the complex impedance and reduce the phase difference between the imaginary and real part of the complex input impedance. It can be seen from the expression (2) below that this will reduce the magnitude of the voltage at the input to the voltage doubler.

$$|V_{load}| = \frac{V_{source}}{2}\sqrt{\frac{|Z_{load}|}{R_{source}\cos(\phi)}} \tag{2}$$

[0056] By switching the order of the capacitor C**1** and the inductor L**1**, as in FIG. **4***b*, the reactive part of the impedance at points D and E is tuned out generating a large resonant voltage across the MOSFET capacitors, resulting in a real impedance on the order of 10 to 100 ohms. This is orders of magnitude lower than any parasitic impedance to the substrate due to C**1**. Therefore, the circuit in FIG. **4***b* shows superior performance to the circuit in FIGS. **3** and **4***a* in the presence of parasitic capacitances from C**1**.

[0057] This improvement can also be understood as follows. If one considers the operation of the resonant voltage generator circuit, one realizes that the largest voltages are generated at point B and the lowest voltage exist at the node connecting inductor L**1** and the source resistor Rs in FIG. **3**. Therefore, in the current embodiment, the parasitic capacitor and parasitic series resistor are moved away from the highest potential in the circuit to the lowest potential in the power harvesting circuit by switching the order of the inductor L**1** and the capacitor C**1**. While this has no effect on the theoretical operation of the circuit with respect to a schematic (done without regard to actual layout and fabrication), it greatly improves actual operation by placing the parasitic elements at a lower voltage where they will draw substantially less current, and thereby minimize their negative impact on power harvesting circuit's operation.

[0058] Another implementation of this concept is performed with the layout of inductor L**1**. The inductor L**1** is implemented on two metal layers of the CMOS process. The lower layer, which is closer to the substrate, gives rise to larger parasitic capacitance and substrate resistance. Therefore, the inductor L**1** is fabricated with the lower layer location placed at the location where the circuit voltage is lowest. This location is the side of inductor L**1** that is closer to the input and specified by point D in FIG. **4***b*.

[0059] It should also be noted that modern processes such as the IBM 8 RF process require that a certain ratio of gate tiedowns to metal area be maintained. Connecting the inductor L**1** directly to the gate of NMOS **2** (e.g., M**2** in FIG. **2**) in a Villard voltage doubler would require an unrealistic number of tiedown contacts. Therefore, this technique is best suited for designs that use a PMOS in place of NMOS **2** as discussed below.

[0060] C. Use of PMOS to Reduce Body Effect

[0061] FIG. **5** illustrates a power harvesting circuit with an NMOSFET (e.g., M**2** in FIG. **2**) replaced with a PMOSFET (PMOS in FIG. **5**). In a steady state, an NMOS **2** (e.g., M in FIG. **2**) will have a source potential that is significantly higher than the body potential. This gives rise to an increase in the threshold voltage of NMOS **2** through the body effect. This causes the diode connected NMOS **2** to turn on at a higher voltage, thereby reducing efficiency. To minimize the body effect in the current embodiment, NMOS **2** is replaced with a diode connected PMOS, as shown in FIGS. **3** and **5**. The PMOS has the body, gate, and drain node connected to Vout and the source node connected to the voltage at the source terminal of the diode connected NMOS **1**. The body effect of NMOS **1** (e.g., M**1** in FIG. **2**) is already minimized and is treated similar to M**1** in FIG. **2**. The PMOS only conducts when the gate voltage is below the source voltage. Since the gate has been connected to Vout, this occurs when the AC voltage at the input is positive with respect to ground. Since both the body and the source of the PMOS are connected to Vout, no threshold voltage increase occurs due to the body effect. This improvement can be combined with the other embodiments discussed above, including the embodiment shown in FIG. **3** where the order of the capacitor C**1** and the inductor L**1** are transposed to reduce parasitic capacitive and resistive losses.

[0062] In order for the design to work, the PMOS needs to be sufficiently isolated to allow connecting the body of the PMOS to Vout without any current flowing from the PMOS body to the bulk substrate. Connecting the body of a diode connected PMOS to Vout is possible due to the fact that PMOS FETs are placed in an n doped well inside of the p substrate.

[0063] As seen in FIG. **6**, the PMOS is built in an N well. Since the junction from the N well to the P substrate acts as a diode, if the voltage potential in the N well is higher than the voltage potential in the P substrate, current will not flow. This is what allows the body to be connected to Vout which is higher than the potential of the substrate. The junction capacitance between the N well and the substrate is parallel to and several orders of magnitude lower than the output capacitance C**2** of the power harvesting circuit. Therefore, the junction capacitance has no significant effect on the circuit performance.

[0064] D. Sacrificial Biasing

[0065] The output voltage of the related art voltage doubler is two times the input voltage minus the threshold voltage of both diodes. Therefore, minimizing the threshold voltage of the diodes maximizes the voltage at the output of the voltage doubler. Previous works in the related art have attempted to improve RF power harvesting efficiency by using special MOSFETS with reduced gate threshold voltages.

[0066] In an exemplary embodiment of the present invention shown in FIGS. **7** and **8**, an alternative technique uses biasing at the gate combined with the use of a PMOS in place of the output NMOSFET to eliminate the threshold voltage for both diode connected MOSFETs.

[0067] For example, in the embodiment shown in FIG. **7**, voltage sources are directly connected to the gates of the diode connected MOSFETs in the RF power harvesting circuit.. An alternative approach is to use the desired output voltage to create the bias voltages through a voltage divider network, as shown in FIG. **8**. This technique sacrifices some current to create an overall improvement to system efficiency. In this embodiment, the NMOS **2** is replaced by a PMOS IN FIG. **8** for two reasons. First, the threshold voltage of the output diode connected MOSFET must be below Vout to be obtainable through a voltage divider network. Second, the gate is connected to a DC node in the circuit. Sufficiently larger resistors R**1**, R**2**, R**3**, and R**4** are used in the divider network IN FIG. **8** to reduce power dissipated due to the bias current. The resistors are chosen to be 1 MΩ to 10 MΩ for 10 μW input power. Generally, the smaller the input power, the higher the resistances. This power dissipation can be designed to be orders or magnitude below the increase in output power due to the bias voltages. Practical limitations are placed on the size of the resistors used in the divider network due to a physical limitation of the resistor size in the circuit layout.

[0068] In the current embodiment, traditional MOSFETs outperform low threshold voltage MOSFETs when sacrificial current biasing is utilized. This is in contrast to related art literature that has concluded that the use of low threshold voltage MOSFETs provides the best performance for RF power harvesting. So, instead of using low threshold voltage MOSFETs, we have introduced sacrificial biasing while using regular MOSFETs and have achieved improved results. The improvement is because we achieve the effect of easily turning on the MOSFETs, while retaining the improved performance of regular MOSFETs with respect to the turn on characteristics as shown in FIG. **9**. Regular MOSFETs, have a sharper turn-on transition than low threshold voltage MOSFETs resulting in a faster turn on when transitioning to the open state, showing better RF conversion efficiency.

[0069] FIG. **10** illustrates a comprehensive design of a power harvesting device which includes the transposition of the inductor L**1** and the capacitor C**1** of FIG. **4***b*, the implementation of the PMOS device in place of M**2** as shown in FIG. **5**, inclusion of sacrificial bias resistors R**1**-R**4** as shown in FIG. **8**, as well as implicit utilization of MOSFET intrinsic capacitors for achieving maximum turn on voltages with low power input as shown in FIG. **3**.

[0070] FIG. **11** is the layout of the harvesters to form a silicon integrated circuit. The layout shows five RF power harvesting circuits, which are the physical implementations of the harvesting circuits shown in the circuit schematics shown in other figures. The circuits have been used to compare and test the various designs of the energy harvester. The testing provided the data that has lead to the conclusion and claims in this patent application.

[0071] FIG. **12** illustrates a comparison of measured RF to DC conversion efficiency versus output voltage between a power harvesting device with sacrificial biasing, and a power harvesting device without biasing. The harvester with sacrificial biasing achieves high efficiency compared with unbiased design for 1V output voltage. The higher curve represents a higher conversion efficiency for RF energy into DC energy. That is, the results show that for the given output voltages, the sacrificial biasing provides improved efficiency over the unbiased design.

[0072] FIGS. **13**-**21** relate to self-powered systems. An RF power harvesting device discussed with respect to the above embodiments is incorporated. Available RF power is sometimes very weak, so it is not easy to generate a sufficient output for direct use. Using a combination block, converter, and battery provides an attractive solution.

[0073] FIG. **13** shows a block diagram of self-powered system including an RF power harvesting block **1**, a voltage converter **2**, a battery **3**, a combined block **4**, and functional electronics **5**. Here, the RF power harvesting block **1** could be one of the RF power harvesting devices discussed in the above embodiments.

[0074] In one embodiment, the converter **2** is a switched-capacitor DC-DC voltage converter. The converter is designed to generate maximum six times of input voltage at output using external capacitors. Through capacitor charging tests, it shows up to 40.5% energy transfer efficiency using 0.35V input for a 1000 uF capacitor charging to 1.4V during 10 minute with a three stage converter. The battery **3** can be a rigid type battery or a flexible type battery. Both types of batteries are successfully recharged using the converter **2**. In one embodiment, two hour charging with four parallel converters recharges a rigid battery fully with 0.4V input, so it returns the battery potential to the initial condition before discharging of a 9.85 KΩ load resistor during 10 minutes.

[0075] The rigid type electrochemical battery comprises hydrated Ruthenium Oxide ($RuO_2.xH_2O$) and activated Carbon (CA). These cells have high current capacity, rechargeability, and even flexibility. One of the targets of the battery **3** is playing a role of the power source for distributed sensor networks, or Smart-dust nodes, for achieving a stand-alone system. Much research in the related art has been focused on implementing self-powered systems such as a node of low-power ad hoc distributed networks using an RF power harvesting device. However, when the input power at RF harvesting block **1** is very small, the output is not enough to drive a system or node (e.g., the functional electronics **5**). This problem can be solved by using a voltage converter **2** and rechargeable battery **3** combination block **4**, as shown in FIG. **13**. For example, a DC voltage converter **2** stacks the small voltage of RF energy harvesting block **1** up to the necessary charging voltage for battery cell and charges a battery **3**. Then, the battery **3** provides enough bias or power for the system (e.g., functional electronics **5**) only when it needs to be working. In the current embodiment, a switched-capacitor DC voltage converter is used as the converter **2** for battery charging. This converter **2** and battery **3** combined block **4** bridges a gap between RF power harvesting block **1** and functional electronics **5**, e.g., in insufficient RF power environments. So, it can help to implement a self-powered or stand alone system more effectively.

[0076] Usually, the developed battery cells have 1.1V~1.2V built in potential after fabrication without any other charging or discharging steps, and slightly higher charging voltage than the built in potential was fine for battery recharging. Actually, charging voltage and time for constant voltage charging scheme show a trade-off relation. A 1.4 charging voltage of DC power supply is used during two hours for full recharging. FIG. **14** shows two types of batteries, a rigid battery (FIG. **14**(*a*)), and a flexible battery (FIG. **14**(*b*)).

[0077] Switched-Capacitor DC-DC Converter

[0078] There are two reasons why we choose a switched-capacitor scheme for DC-DC converter among several different types. The first is its simplicity of implementation, and the second is it needs capacitors for storing energy. The second factor is advantageous because the battery cells can be used as a capacitor also by some modifications. So the switched-capacitor method is a very attractive one.

[0079] FIG. **15**(*a*) shows the schematic of a switched capacitor DC-DC converter with three stages. A single chip is implemented using IBM8RF 0.13 um CMOS process including every switch for a five stage converter, except external capacitors. That is, maximum available output voltage is six times of input voltage through five external capacitors, and the output can be selected by a user from minimum (input×1) to maximum (input×6) just connecting an external capacitor's plus pad to input.

[0080] In the schematic, the top switches are made by nMOS only, but the middle and bottom switches are made by transmission gate, combining nMOS & pMOS to transfer the accumulated potential on each capacitor to the next stage without any loss. The converter works on two different phases. For capacitor storing phase ($Q=1$, $\overline{Q}=0$ FIG. **15**(*b*)), the input node is connected to every external capacitor, so all capacitors are in parallel. However, the output is disconnected from the converter. In this step, external capacitors are charged up through input. Then, during battery charging phase (Q=0, $\overline{Q}$=1,

[0081] FIG. **15**(*c*)), the parallel configuration of capacitors is changed into series, and the output is connected to the last capacitor's plus node. Note the input can be used in both phases without any waiting or sleeping mode. So, it can decrease the charging time by fully using the input source. FIG. **16** shows the output (~1.4V) of the converter using a three stage converter for 0.35V input at 20 Hz clock signal using 100 uF three external capacitors. Note the body contacts of pMOS in converter switches are connected into external 1.5V DC power supply. This external source can be replaced with a battery for fully self-powered system implementation.

[0082] Big Capacitor Charging

[0083] At the initial tests of the converter, a big capacitor, 1000 uF, replaces a battery for charging test to verify functionality of the converter, just using three stages. Also, frequency dependency is checked for different clock signals of 50% duty cycle. The external capacitors, storing energy from input voltage, and input voltage are fixed as 100 uF and 0.35V, respectively. FIG. **17** shows the results of capacitor charging for different clock signals, and the inner graph is a magnified version of 400~700 sec section. All tests are stopped when the capacitor voltages reach 1.38V, except 20 KHz test. The plots for 2 Hz, 20 Hz, and 200 Hz test are almost overlapped. As listed in Table 1, 2 Hz and 20 Hz test have almost same results for energy transfer efficiency, around 40%, and charging time about 10 minutes, where the supplied energy is calculated by integrating the measured current from power supply and the stored energy is just calculated value using ½CV^2. As the clock frequency goes higher, the saturation voltage goes lower. It is caused by frequency dependency of dynamic power consumption of CMOS switches [6]. By frequency dependency tests, a 0.2 Hz~20 Hz clock frequency range is used for battery charging tests.

TABLE 1

Frequency dependency of 1000 uF capacitor charging properties

Clock Frequency [Hz]	Charging Time [sec]	Supplied Energy [mJ]	Stored Energy [mJ]	Energy Transfer Efficiency [%]
0.2	953.5	2.352	0.952	40.48
2	611.5	2.349	0.952	40.53
20	617.5	2.394	0.952	39.77
200	629.5	2.555	0.953	37.30
2K	755.5	2.755	0.953	34.59
20K*	755.5	3.010	0.852	28.31

*For 20 KHz test, 1.3 V saturated voltage is used for calculations.

[0084] Battery Charging

[0085] The test procedure follows three steps for battery charging: 1) initial discharging, 2) cell charging, and 3) discharging.

[0086] The first charging test set up is 0.3V input from power supply, five 100 uF external storing capacitors for a five stage converter, which provides 1.8V output without load, and 50% duty cycle 0.2 Hz clock signal. Actually, a test with 0.25V input, making 1.5V output by five stages, was performed, but the charging time took over several days. So, to reduce charging time, input voltage is increased from 0.25V to 0.3V. FIG. **18** shows the test results. After the initial discharging (dashed line) during 1280 seconds, the load voltage was dropped from 0.485V to 0.223V for 1 KΩ load resistor. The black solid line shows the discharging after 60 hours charging. 60 hours charging gives 0.316V initial load voltage, when 1 KΩ load is connected to the battery after charging. Though the charging time, 60 hours, is a little long, we demonstrate a DC-DC converter is working properly for the battery charging.

[0087] To reduce charging time, the input voltage is increased from 0.3V to 0.34V and two converters are used in parallel for another test. Clock signals are applied for two converters to operate in opposite mode at the same time. That is, if a converter is in capacitor storing mode, the other is in battery charging mode. The test setup is 0.34V input, generating 2V output without load due to using five stage, and 25 Hz clock signal with 50% duty cycle. The battery cell is discharged with 1 KΩ load during 20 minute before charging, as shown by the dashed line in FIG. **19**, and load voltage drop is measured from 0.358V to 0.174V. Then, two converters charge the cell for 4 hours. This leads to 0.29V initial load voltage at discharging after charging (solid line in FIG. **19**). Using higher input voltage and two converters, the charging time is effectively reduced from 60 hour to 4 hour.

[0088] Another charging test is performed using four converters for further decreasing charging time. To run four converters together, switching signals are generated using a ring counter, which is made by four D Flip-Flops. FIG. **20** shows the generated timing diagram of the counter, Q_0~Q_3. Simply, inverters inverse each timing signal for the reverse switching signal inputs, $\overline{Q_0}$~$\overline{Q_3}$. Using the switching signals, if Q_0 is high, only one output of converters is connected to battery cell, and the others are in capacitor storing mode.

[0089] During capacitor storing mode, external capacitors are in parallel, so it gives a high total capacitance. Accordingly, it makes a long RC time constant for capacitor storing. Previous tests used five stages with 100 uF external capacitor, which gave 500 uF total capacitance for capacitor storing mode. For quick charging up capacitors, only three stages are used for other tests, which need three external capacitors for each converter. However, reducing the number of stage affects the output voltage directly. To compensate for this, higher input voltage is used. Also, higher input voltage can reduce the charging time further by providing more charges on storing capacitor, if the current capacity of the input signal is not limited. In the following tests, 0.35V, 0.4V, and 0.45V input are used for comparison.

[0090] Four charging tests are performed using a rigid (Test 1~3) and flexible (Test 4) type battery. For a rigid battery, charging time is limited to 2 hour, but the flexible cell is charged for 12 hours due to the cell's own property. Usually, the flexible battery consumed more current at the same charging voltage compared with rigid one. Furthermore, 9.85 KΩ and 100.2Ω load resistor are used at discharging for rigid and flexible battery, respectively. The test results and setup are shown in FIG. **21** and Table 2.

[0091] Every charging test shows energy recovery of battery. Although 2 hour charging with 0.35V input is not sufficient for full recovery before discharging, other two tests, Test 2 & 3, show the fully recovered battery potential compared with discharging before charging tests. However, Test 3 does not give any improvement in spite of higher input voltage, 0.45V. This may be due to the aging of the cell through several charging and discharging tests. Test 4 shows 12 hour charging result for flexible cell.

TABLE 2

Charging test setup and results

			Charging (three stage converter)			Discharging during 10 minutes				
							Before charging [V]		After charging [V]	
Test #	Battery Cell Type	Battery Cell Size	Input [V]	Clock [Hz]	Charging time [Hour]	Load resistor [Ω]	Initial load voltage	Final load voltage	Initial load voltage	Final load voltage
1	Rigid	4 cm^2	0.35	20	2	9.85K	0.804	0.659	0.759	0.612
2	Rigid	4 cm^2	0.4	20	2	9.85K	0.790*	0.648	0.804	0.659
3	Rigid	4 cm^2	0.45	20	2	9.85K	0.818	0.688	0.828	0.701
4	Flexible	4 cm^2	0.45	2	12	100.2	0.775	0.497	0.689	0.445

*Initial load voltage for Test 3 before charging is estimated value because of a slacken load connection.

[0092] As described above with respect to FIGS. **13-21**, a switched-capacitor DC-DC converter is implemented using a CMOS process for a battery cell charging application. Up to 40% energy transfer efficiency is obtained through capacitor charging tests. For battery cell charging tests, the functionality of the converter is verified for both rigid and flexible type battery cells using much smaller input voltage compared with general high charging voltage, more than 1.2V for the batteries discussed with respect to FIGS. **13-21**.

[0093] The techniques described above show a dramatic increase in power harvesting efficiency as compared to existing RF Power Harvesting designs and, enable recharging portable wireless electric using ambient RF energy sources. Utilizing these improvements, a design goal of generating 1V output voltage with a greater than 20% RF to DC conversion efficiency from RF energy levels measured in the environment (66 uW) was met. This represents better than double the RF to DC conversion efficiency of the related art power matched RF energy harvesting circuit based on a Villard voltage doubler.

[0094] Several design improvements, novel to RF power harvesting circuits, have been disclosed. These improvement include RF to DC conversion efficiency through a reduction in the body effect of diode connected MOSFETs, reduction in the threshold voltage and by reducing the affects of circuit parasitics. These circuit improvements have been simulated to show a better than 60% improvement to RF to DC conversion efficiency.

[0095] While the present invention has been particularly shown and described with reference to exemplary embodiments thereof, it will be understood by one of ordinary skill in the art that various changes in form and details may be made therein without departing from the spirit and scope of the present invention as defined by the following claims.

1. An RF power harvesting device comprising:
an inductor;
a first capacitor connected to the inductor;
a first MOSFET connected to a first node, and
a second MOSFET connected to the first node,
wherein the inductor or the first capacitor are connected to the first node.

2. The RF power harvesting device of claim **1**, wherein values of the first MOSFET and the second MOSFET are such that intrinsic capacitances of the first MOSFET and the second MOSFET and the inductor constitute a substantially resonant circuit during operation of the RF power harvesting device.

3. The RF power harvesting device of claim **1**, further comprising:
a second capacitor connected to a second node, and the second MOSFET is connected to the second node,
wherein the second MOSFET is a PMOSFET.

4. The RF power harvesting device of claim **1**, further comprising:
a receiver which detects and receives ambient RF energy,
wherein the first capacitor and the receiver are connected at a third node, the first capacitor and the inductor are connected in series at a fourth node, and the inductor is connected to the first node.

5. The RF power harvesting device of claim **1**, further comprising:
a first set of resisting elements connected to a first gate of the first MOSFET to apply a first DC bias to the first gate; and
a second set of resisting elements connected to a second gate of the second MOSFET to apply a second DC bias to the second gate.

6. A receiver comprising:
an impedance matching circuit connected to a first node;
a first MOSFET connected to the first node; and
a second MOSFET connected to the first node, wherein
the first MOSFET is a diode-connected p type MOSFET.

7. The receiver of claim **6**, wherein the impedance matching circuit comprises an inductor and a capacitor in series, the inductor connected to the first node.

8. The receiver of claim **6**, wherein a resistive biasing network provides a bias voltage to gate terminals of the first MOSFET and the second MOSFET.

9. A system comprising:
a receiver;
a voltage converter; and
an energy storage device, wherein
the receiver is configured to receive a high frequency signal and supply a first voltage to the voltage converter, and
the voltage converter is configured to amplify the first voltage supplied by the receiver and supply the amplified voltage to the energy storage device.

10. The system of claim **9**, wherein the voltage converter includes a switched capacitor circuit.

(57) **ABSTRACT**

A patch antenna for receiving high frequency wireless signal and a rectenna using the same, more particularly, an impedance-matched patch antenna adopting a slot capacitive coupling structure and a rectenna capable of generating electrical energy from the wireless signals having different frequency band. A rectenna for receiving an A.C. wireless signal carrying electrical energy and converting the wireless signal into a D.C. electrical energy, is comprised of: a patch antenna for receiving the wireless signal comprising an dielectric substrate, a patch that is formed at the upper area of the surface of the dielectric substrate and providing the first frequency response characteristics, a ground plane formed on the other surface of the dielectric substrate, and an impedance matching means providing the second frequency response characteristics; and a rectifying unit that converts the wireless signal, received via the patch antenna, into a D.C. electrical energy by rectifying the wireless signal.

PATCH ANTENNA AND RECTENNA USING THE SAME

BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] This invention relates to a patch antenna for receiving high frequency wireless signal and a rectenna using the same, more particularly, to an impedance-matched patch antenna adopting a slot capacitive coupling structure and a rectenna capable of generating electrical energy from the wireless signals having different frequency band.

[0003] 2. Description of the Related Art

[0004] A patch antenna according to the first example of prior art is illustrated in FIG. **1**. A patch antenna **10** illustrated in FIG. **1** adopts an in-set structure, wherein impedance matching is achieved by adjusting design parameters (a, b) of the gap **122** formed at each side of the feeder line **121** that is a partial extension from the bottom side of the patch **12** which is formed on a surface of the dielectric substrate **11**.

[0005] According to the first example of prior art, forming the minute gaps at both sides of the feeder line **121** is a very difficult process; furthermore, the impedance matching condition gets easily out of control due to a small variation in process parameters during actual fabrication of a patch antenna.

[0006] In addition, since the gaps **122**, located at the both sides of the feeder line **121** which is an impedance matching means, are formed inside the patch **12** as an integrated part thereof, the expensive patch **12** has to be newly fabricated in case when a problem occurs during the gap forming process.

[0007] A patch antenna according to the second example of prior art is illustrated in FIG. **2**. The patch antenna **20**, having a dual frequency band characteristics, of the second example of prior art is comprised of an dielectric substrate **21**, an external patch **22**, and an internal patch **23** as illustrated in FIG. **2**.

[0008] The patch antenna **20** of the second example of prior art is capable of transmitting and receiving both signals having two different frequency bands by adopting an external patch **22** and an internal patch **23** having different frequency characteristics.

[0009] But, since this type of patch antenna utilizes two patches in transmitting and receiving signals having two different frequency bands, it requires high production cost and large antenna size to integrate two types of patch into a stacked form.

[0010] A rectenna according to an example of the prior art is illustrated in FIG. **3**. The rectenna **30**, shown in FIG. **3**, relates to a rectenna that utilizes a loop antenna; it is largely comprised of a loop antenna **31** and a rectifying circuit **32**; it converts an A.C. wireless signal received via the loop antenna **31** into a D.C. electrical energy by rectifying the A.C. wireless signal in the rectifying circuit **32**, and supplies this electrical energy to the load **33**.

[0011] Since such rectenna **30** of the prior art has only one frequency characteristics depending on the characteristics of the loop antenna **31**, the electrical energy cannot be supplied to the load **33** if a wireless signal having the frequency band matched in frequency characteristics of the rectenna **30** is not received.

[0012] Furthermore, the rectenna **30** of the prior art simply rectifies the received wireless signal, so the wireless signal must be amplified before transmitting the wireless signal to the rectenna **30** when the load **33** needs a high voltage.

BRIEF SUMMARY OF THE INVENTION

[0013] The first objective of this invention, to solve above-described problems, is to provide a patch antenna having structures for an easy impedance matching.

[0014] The second objective of this invention is to provide a dual-band patch antenna having dual-band signal characteristics using a single patch.

[0015] The third objective of this invention is to provide a dual-band patch antenna capable of transmitting and receiving a circularly polarized wave and a linearly polarized wave in two different frequency bands.

[0016] The fourth objective of this invention is to provide a rectenna capable of generating an additional electrical energy by receiving non-relevant signals such as Wi-Fi or Bluetooth signal existing in free space mixed with the signals which are generally utilized for wireless power transmission.

[0017] The fifth objective of this invention is to provide a rectenna capable of generating higher voltage than that of the rectified energy obtained by rectifying the input signal from the voltage multiplying circuit.

[0018] Other objectives and advantages of the present invention will be described hereinafter and become apparent through the exemplary embodiments of the present invention. The objectives and advantages of the present invention can be accomplished through the means and combination of the elements of the claims.

[0019] A patch antenna in accordance with a preferred exemplary embodiment of the present invention to solve above-described problems is comprised of: an dielectric substrate; a patch that is formed on the first surface of the dielectric substrate and assigns the first frequency characteristics; and a ground plane that is formed on the second surface of the dielectric substrate, wherein an impedance matching means, that is capacitively coupled with the patch, is formed on the one side of the ground plane.

[0020] According to the patch antenna of the present invention, it is preferred that the impedance matching means is comprised of: a slot formed in the bottom area of the ground plane; and a feeder line formed inside of the slot and being separated by a predetermined distance therefrom.

[0021] According to the patch antenna of the present invention, it is preferred that the feeder line is formed at a location where the feeder line can face the bottom area of the patch with the dielectric substrate interposed between one end of the feeder line and the patch.

[0022] According to the patch antenna of the present invention, it is preferred that the slot and the feeder line is to be formed in a T-shaped pattern, wherein the feeder line is formed at a location where the bar-shaped head of the feeder line can face the bottom area of the patch so as to provide the second frequency response by adjusting the size of the slot and the feeder line.

[0023] According to the patch antenna of the present invention, the patch may be a hexagonal shape formed by etching off two facing corners of a square.

[0024] Meanwhile, a rectenna in accordance with a preferred exemplary embodiment of the present invention, for receiving an A.C. wireless signal carrying electrical energy and converting the wireless signal into a D.C. electrical energy, is comprised of: a patch antenna for receiving the wireless signal comprising an dielectric substrate, a patch that is formed at the upper area of the surface of the dielectric substrate and characterizing the first frequency response characteristics, a ground plane formed on the other surface of the dielectric substrate, and an impedance matching means characterizing the second frequency response characteristics; and a rectifying unit that converts the wireless signal, received via the patch antenna, into a D.C. electrical energy by rectifying the wireless signal.

[0025] According to the rectenna of the present invention, it is preferred that the rectifying unit is comprised of a voltage multiplying circuit that comprises multiple capacitors and diodes and at least two of serially connected rectifying and multiplying stages so as to convert the wireless signal into an electrical energy by rectifying the wireless signal and multiply the voltage of the converted electrical energy simultaneously.

[0026] Besides, according to the rectenna of the present invention, it is preferred that the rectifying unit is further comprised of: a grounding area that is being separated from the ground plane of the patch antenna; and a bead for suppressing the effect of the A.C. signal and located between the grounding area and the ground plane of the patch antenna.

[0027] According to the rectenna of the present invention, the bead may further include an inductor.

[0028] According to the rectenna of the present invention, it is preferred that the rectifying unit is installed on the same plane of the ground plane of the patch antenna.

[0029] According to the antenna of the present invention, a capacitive coupling between the patch and the feeder line is obtained through the structure wherein the slot is formed on the ground plane and the feeder line is formed inside of the slot; when compared to the patch antennas of conventional technology, more easy impedance matching can be achieved by adjusting the design parameters of the slot and the feeder line on the ground plane; therefore, additional fabrication of another expensive patch can be avoided even in the worst-case.

[0030] According to the antenna of the present invention, it has the advantage that the production cost can be reduced by using a single patch instead of two patches; even though it has a dual-band frequency response, the size of the antenna may not be increased because another frequency response different than that of the patch is provided through adjustment of the design parameters of the T-shaped slot and the T-shaped feeder line.

[0031] According to the antenna of the present invention, it has the advantage that it can handle various signals since a circularly polarized wave and a linearly polarized wave can be transmitted and received in two different frequency bands.

[0032] According to the rectenna of the present invention, it has the advantage that it can supply more stable power compare to the conventional rectenna since it can generate an additional electrical energy by receiving non-relevant signals such as Wi-Fi or Bluetooth signal existing in free space mixed with the signals which are generally utilized for wireless power transmission.

[0033] According to the rectenna of the present invention, it has the advantage that it can be applied to various equipments because higher voltage than that of the input signal can be obtained through two-stage voltage multiplication in the rectifying unit.

[0034] According to the rectenna of the present invention, it has the advantage that the space required to install a rectenna can be reduced since the overall size can be reduced by forming the rectifying unit on the ground plane of the antenna.

BRIEF DESCRIPTION OF THE DRAWINGS

[0035] FIG. **1** is a schematic diagram of a patch antenna in accordance with a conventional technology;

[0036] FIG. **2** is a schematic diagram of a patch antenna in accordance with another conventional technology;

[0037] FIG. **3** is a schematic diagram of a rectenna in accordance with a conventional technology;

[0042] FIG. **8** is a schematic diagram of a rectenna in accordance with a preferred exemplary embodiment of the present invention;

[0043] FIG. **9** is a detailed circuit diagram of the rectifying unit shown in FIG. **8**; and

[0044] FIG. **10** is an example graph illustrating the simulated output values of the rectifying unit as a result of the voltage multiplication.

DETAILED DESCRIPTION OF THE INVENTION

[0045] Hereinafter, preferred exemplary embodiments of the present invention will be described in detail with reference to the attached drawings. Terminology and word used in the description and the claims of the present invention should not be construed as a typical or a lexical meaning, but construed as a meaning and concept in accordance with the technical spirit of the present invention on the basis of the principle that the inventors may properly define the concept of a terminology in order to best describe his/her invention.

[0046] Therefore, it should be understood that a variety of equivalents and modification examples that can replace the exemplary embodiments and configurations described in the drawings may exist at the time of this patent application since these exemplary embodiments and configurations are only a few examples of the present invention and not representing all the technical spirits of the present invention.

[0047] Hereinafter, a patch antenna and a rectenna in accordance with the present invention will be described with reference to the attached drawings.

[0048] FIG. **4** is a schematic diagram of a patch antenna in accordance with a preferred exemplary embodiment of the present invention. As illustrated in FIG. **4**, the patch antenna **41** in accordance with a preferred exemplary embodiment of the present invention, similar to conventional patch antenna, is comprised of an dielectric substrate **411**, a patch **412** that is formed on a surface of the dielectric substrate **411**, and a ground plane **413** that is formed on the other surface of the dielectric substrate **411**.

[0049] The dielectric substrate **411**, where a patch **412** and a ground plane **413** is formed on the opposite surface thereof facing each other, is made of a non-conducting dielectric material as the name implies.

[0050] Since this exemplary embodiment is based on the dielectric substrate **411** having thickness of 1 mm, the result of the following experiment can be affected if the thickness of the dielectric substrate **411** is different.

[0051] The patch **412** is the most essential element that determines the operating frequency of the patch antenna **41** according to the size and the shape of the patch **412**; it is formed in the upper area of the first surface of the dielectric substrate **411** and provides the frequency response of the patch antenna **41**. The patch antenna **41**, for example, having a 29 mm square patch **412** may exhibit a linear polarized wave characteristics for frequencies around 2.4 GHz.

[0052] The patch antenna **41** of the present invention is for transmitting and receiving linearly polarized waves, and it is preferred to form the patch **412** in a square shape for transmitting and receiving such linearly polarized waves.

[0053] The ground plane **413** is formed on the other side of the patch **412**, in other words, on the other surface of the dielectric substrate **411**; in the present invention, the feeder line **4142** is formed on the same plane as the ground plane **413** in order to form a coplanar waveguide (CPW) structure.

[0054] In a preferred exemplary embodiment of the present invention as shown in FIG. **4**, an impedance matching means **414** is formed inside of the ground plane **413**, and the impedance matching means **414** is comprised of: a slot **4141** formed along the length direction of the ground plane **413**; and a feeder line **4142** formed inside of the slot **4141** and being separated by a predetermined distance therefrom.

[0055] In here, the feeder line **4142** should be formed at a location where the feeder line can face the bottom area of the patch **412** with the dielectric substrate **411** interposed between one end of the feeder line and the patch.

[0056] Through above-described configuration of the present invention, the capacitive coupling between the feeder line and the patch is being accomplished.

[0057] According to the exemplary embodiment of the present invention, an easy impedance matching can be obtained by adjusting the design parameters of the ground plane using such configuration.

[0058] FIGS. **5***a* and **5***b* illustrate an example of return loss varying with the values of F and A, shown in FIG. **4**, that are the design parameters of the antenna in accordance with the present invention.

[0059] As shown in FIGS. **5***a* and **5***b*, impedance matching can be achieved at frequencies around 2.4 GHz by adjusting the values of design parameters of F and A of the slot **4141** and the feeder line **4142**; according to the simulation results, a return loss of near −30 dB can be obtained at frequencies around 2.4 GHz.

[0060] Table 1 provides examples of values of design parameters that are being adjusted so that a patch antenna in accordance with the present invention could have a linearly polarized wave characteristics at frequencies around 2.4 GHz

TABLE 1

design parameter	value [mm]	design parameter	value [mm]
W	29	A	7
L	29	B	17
X	43	U	1.865
Y	36	F	16

[0061] According to a patch antenna in accordance with a preferred exemplary embodiment of the present invention, it has the advantage that the variations in the frequency response characteristics caused by the tolerances are less pronounced compare to conventional in-set type structures; impedance matching can be achieved by simply adjusting the design parameters of the slot and the feeder line on the ground plane; therefore, additional fabrication of another patch can be avoided even when an impedance matching is failed.

[0062] A patch antenna **51** in accordance with another preferred exemplary embodiment of the present invention is illustrated in FIG. **6**.

[0063] A patch antenna having two kinds of frequency band characteristics is provided in the another preferred exemplary embodiment of the present invention.

[0064] To achieve above-described capability, a patch antenna **51** in accordance with another preferred exemplary embodiment of the present invention is comprised of an impedance matching means **514** that is formed on the ground plane **513** and comprising a T-shaped slot **5141** and a T-shaped feeder line **5142** as shown in FIG. **6**.

[0065] A patch antenna **51** in accordance with another preferred exemplary embodiment of the present invention enables an impedance matching by adjusting the design parameters of the T-shaped slot **5141** and the T-shaped feeder line **5142** as shown in FIG. **6**; in addition, a dual-band patch antenna in accordance with the present invention can obtain previously mentioned second frequency response characteristics by adjusting the design parameters of the T-shaped slot **5141** and the T-shaped feeder line **5142**, more particularly, by adjusting the values of the design parameters B, X, and M.

[0066] Table 2 provides examples of values of antenna design parameters that are being adjusted so that the patch antenna could have an additional frequency response characteristics at frequencies around 3.1 GHz

TABLE 2

design parameter	value [mm]	design parameter	value [mm]	design parameter	value [mm]
W	23.5	A	33	y	1.5
L	23.5	B	4	U	1.865
W'	3.5	C	14	M	15.4
L'	3.5	X	8	M'	14.5

[0067] According to another preferred exemplary embodiment of the present invention, a patch **512** can be a hexagonal shape formed by etching off two facing corners of a square as shown in FIG. **6**; a patch antenna adopting such type of patch possesses a circularly polarized wave characteristics at frequencies around 2.4 GHz reflecting the design parameters of the particular patch shape, and possesses a linearly polarized wave characteristics at frequencies around 3.1 GHz reflecting the design parameters of the ground plane, but showing independence in patch size.

[0068] Through the above-described configuration, a patch antenna in accordance with another preferred exemplary embodiment of the present invention can handle not only two different frequency band signals, but also two different polarization types (i.e. a circular and a linear polarization).

[0069] Hereinafter, a rectenna in accordance with a preferred exemplary embodiment of the present invention will be described with reference to FIG. **8**. In the following description, an element with the symbol number quoted from FIG. **6** is considered as equivalent as a corresponding element in FIG. **4** performing same function as the function of the corresponding element in FIG. **6**, and vice versa.

[0070] FIG. **8** is a schematic diagram of a rectenna in accordance with a preferred exemplary embodiment of the present invention. A rectenna **50** in accordance with a preferred exemplary embodiment of the present invention is comprised of a patch antenna **51** and a rectifying unit **52** as shown in FIG. **8**.

[0071] Since the patch antenna **51** in FIG. **8** has same function and configuration as the patch antenna shown in FIGS. **4** and **6**, it will not be described hereinafter.

[0072] The rectifying unit **52** rectifies wireless signals received via the patch antenna **51**, and converts the rectified signal into an electrical energy.

[0073] The rectifying unit **52** can be integrated on the same planar surface with the patch antenna **51** using the bottom area of the ground plane **513** of the patch antenna **51** as shown in FIG. **8**; using such configuration, the total area of the rectenna **50** of the present invention can be reduced.

[0074] Meanwhile, a detailed circuit diagram of the rectifying unit **52** is shown in FIG. **9**. As shown in FIG. **9**, the rectifying unit **52** is comprised of multiple capacitors C**1** to C**4** and multiple diodes D**1**, to D**4**, wherein at least two rectifying and multiplying stages A**1** and A**2**, storing electrical energy by rectification effect, are serially connected, and the wireless signal received via the patch antenna **51** is rectified and converted into a D.C. electrical energy and the voltage is multiplied simultaneously.

[0075] More particularly, the rectifying unit **52** in accordance with the present invention is comprised of at least two rectifying and multiplying stages A**1** and A**2**.

[0076] Individual rectifying and multiplying stages have capacitors C**1**, C**2** and C**3**, connected between the serially connected diodes for temporary storage, and the storage capacitor C**4**; in addition, the rectifying and multiplying stages have forward biased diodes D**1** and D**3**, and reverse biased diodes D**2** and D**4** with respect to the ground G.

[0077] When the input voltage is reverse direction (i.e. negative potential with respect to the ground), diodes D**2** and D**4** are turned on so as to charge C**1** and C**2** with electrical energy; later, when the input voltage is forward direction (i.e. positive potential with respect to the ground), electrical energy input coming through the forward biased diodes D**1** and D**3** is simultaneously superimposed on the discharging electrical energy from the capacitors C**1** and C**2** thereby voltage multiplication is achieved.

[0078] Each output voltage from each rectifying and multiplying stage is stored in the capacitors C**3** and C**4**, and the electrical energy stored in the capacitor C**3** eventually flows into the capacitor C**4** due to the serially connected circuit configuration; therefore, the final voltage of the electrical energy stored in the capacitor C**4** is much higher than the initial input voltage to the rectifying unit **52**.

[0079] Although a rectifying unit configuration having only two rectifying and multiplying stages connected each other is described in this exemplary embodiment of the present invention, higher output voltage can be easily achieved by simply connecting more number of rectifying and multiplying stages.

[0080] The graphs illustrating the results of rectification and multiplication of the received wireless signal is shown in FIG. **10**.

[0081] As shown in FIG. **10**, a higher output voltage can be obtained through voltage multiplication by using wireless signal in each individual frequency band, i.e. 2.4 GHz or 3.1 GHz; much higher output voltage can be obtained by using wireless signals in both frequency bands.

[0082] Meanwhile, the rectifying unit **52** comprises a grounding area G that is isolated from the ground plane **513** of the patch antenna **51**, and may further comprise a bead **53** between the grounding area G of the rectifying unit **52** and the ground plane **513** of the patch antenna **51** as shown in FIG. **8**.

[0083] The bead **53** may comprise an inductor; undesirable effects between RF and DC signals can be suppressed by such bead.

[0084] In the rectenna **50**, for a good grounding of the rectifying unit **52**, it is desirable that the grounding area G of the rectifying unit **51** is connected to the ground plane **513** that is the largest conductor; but direct connection of the ground of the patch antenna **51** that handles RF signal to the grounding area G of the rectifying unit **52** that handles D.C. signal could cause a change in the circuit characteristics deviating from the designers intention.

[0085] To prevent such problems, the ground plane **513** and the grounding area G is connected by an inductor so that the ground plane **513** and the grounding area G is electrically disconnected from each other for an A.C. signal while the ground plane **513** and the grounding area G is electrically connected to each other for a D.C. signal.

[0086] Through the above-described configuration, the rectifying unit **52** can be effectively grounded and undesirable changes in the circuit characteristics of the patch antenna **51** can be prevented too.

[0087] According to the previously described rectenna of the present invention, the rectenna converts received main wireless signal of linearly polarized wave into an electrical energy for supplying power in 3.1 GHz frequency band; at the same time, the rectenna additionally generates an electrical energy by receiving circularly polarized wireless signals in 2.4 GHz frequency band such as Wi-Fi, Bluetooth, or DMB signal; therefore, more stable and smooth power can be supplied even in case the reception of the main wireless signal is rather poor.

[0088] Although the present invention herein has been described in the above with reference to the exemplary embodiments, it will be apparent to those skilled in the art that various changes and modification may be made to the above described embodiments, without departing from the scope and spirit of the present invention as disclosed in the accompanying claims.

What is claimed is:

1. A patch antenna comprising:

an dielectric substrate;

a patch that is formed on the first surface of the dielectric substrate and provides the first frequency characteristics; and

a ground plane that is formed on the second surface of the dielectric substrate, wherein an impedance matching means, that is capacitively coupled with the patch, is formed on the one side of the ground plane.

2. The patch antenna according to claim **1**, wherein the impedance matching means is comprised of:

a slot formed in the bottom area of the ground plane; and

a feeder line formed inside of the slot and being separated by a predetermined distance therefrom.

3. The patch antenna according to claim **2**, wherein the feeder line is formed at a location where the feeder line can face the bottom area of the patch with the dielectric substrate interposed between one end of the feeder line and the patch.

4. The patch antenna according to claim **3**, wherein the slot and the feeder line is to be formed in a T-shaped pattern,

wherein the feeder line is formed at a location where the bar-shaped head of the feeder line can face the bottom area of the patch so as to provide the second frequency characteristics by adjusting the size of the slot and the feeder line.

5. The patch antenna according to claim **4**, wherein the patch is a hexagonal shape formed by etching off two facing corners of a square.

6. A rectenna for receiving an A.C. wireless signal carrying electrical energy, and converting the wireless signal into a D.C. electrical energy, comprising:

a patch antenna for receiving the wireless signal comprised of a dielectric substrate, a patch that is formed at the upper area of the surface of the dielectric substrate and provides the first frequency response characteristics, a ground plane formed on the other surface of the dielectric substrate, and an impedance matching means that provides the second frequency response characteristics; and

a rectifying unit for converting the wireless signal, received via the patch antenna, into a D.C. electrical energy by rectifying the wireless signal.

7. The rectenna to claim **6**, wherein the rectifying unit is comprised of a voltage multiplying circuit that comprises at least one capacitor and diode and at least two of serially connected rectifying and multiplying stages capable of storing energy temporarily so as to convert the wireless signal into an electrical energy by rectifying the wireless signal and multiply the voltage of the converted electrical energy simultaneously.

8. The patch antenna according to claim **6**, wherein the rectifying unit is further comprised of:

a grounding area that is being separated from the ground plane of the patch antenna; and

a bead that is located between the grounding area and the ground plane of the patch antenna for suppressing the effect of the A.C. signal.

(57) **ABSTRACT**

Embodiments of a tunable radio frequency (RF) diplexer and methods of operating the same are disclosed. In one embodiment, the RF diplexer includes a first hybrid coupler, a second hybrid coupler, an RF filter circuit, and a phase inversion component. Both the RF filter circuit and the phase inversion component are connected between the first hybrid coupler and the second hybrid coupler. The phase inversion component is configured to provide approximately a differential phase. The RF filter circuit is configured to provide a passband and a notch. The RF filter circuit is tunable to provide the notch on both a high-frequency side of the passband and a low frequency side of the passband. Accordingly, the tunable RF diplexer provides lower insertion losses and higher isolation regardless of whether the one of the diplexed frequency bands is set at higher frequencies or lower frequencies than the other diplexed frequency band.

RF DIPLEXER

RELATED APPLICATIONS

[0001] This application claims the benefit of provisional patent application Ser. No. 61/906,622, filed Nov. 20, 2013, the disclosure of which is hereby incorporated herein by reference in its entirety.

[0002] This application is a continuation-in-part of U.S. patent application Ser. No. 14/523,065, filed Oct. 24, 2014; which claims the benefit of provisional patent application 61/895,386, filed Oct. 24, 2013; the disclosures of which are hereby incorporated herein by reference in their entirety.

FIELD OF THE DISCLOSURE

[0003] This disclosure relates generally to radio frequency (RF) diplexers and diplexing methods for RF front-end modules.

BACKGROUND

[0004] A radio frequency (RF) diplexer is a device that facilitates communication of two different RF signals within two different RF communication bands by a common antenna. For example, with respect to RF receive diplexing, an RF diplexer is configured to receive two different RF receive signals on a common antenna and then route each of the respective RF receive signals to their appropriate ports. With respect to RF transmission diplexing, an RF diplexer is configured to transmit two different RF transmission signals from different ports and route both to the common antenna. In order to facilitate simultaneous diplexing over the antenna, the RF diplexer needs to be designed for operation at both RF communication bands while providing adequate isolation between the different RF communication bands and the different RF signals. Many previously known RF diplexer topologies struggle to provide this isolation, particularly at the high RF communication bands required by modern RF front-ends. Furthermore, while there are tunable RF diplexers that provide diplexing with respect to various combinations of different RF communication bands, these tunable RF diplexers struggle to provide adequate broadband isolation across large portions of the RF frequency spectrum.

[0005] Accordingly, RF diplexers are needed that not only provide high isolation but also maintain this high isolation along greater portions of the RF frequency spectrum.

SUMMARY

[0006] Embodiments of a tunable radio frequency (RF) diplexer and methods of diplexing transmission and receive signals are disclosed. In one embodiment, the RF diplexer includes a first hybrid coupler, a second hybrid coupler, an RF filter circuit, and a phase inversion component. Both the RF filter circuit and the phase inversion component are connected between the first hybrid coupler and the second hybrid coupler. In some embodiments, the phase inversion component is provided by the RF filter circuit, while in other embodiments, the phase inversion component is provided separately. In one embodiment, the RF filter circuit is configured to provide a passband and a notch. The RF filter circuit is tunable to provide the notch on both a high-frequency side of the passband and a low frequency side of the passband. The benefit of allowing the notch to be placed on both the high-frequency side and the low-frequency side of the passband is that the tunable RF diplexer provides lower insertion losses and higher isolation regardless of whether the one of the diplexed frequency bands is provided at higher frequencies or lower frequencies than the other diplexed frequency band.

[0007] Those skilled in the art will appreciate the scope of the present disclosure and realize additional aspects thereof after reading the following detailed description of the preferred embodiments in association with the accompanying drawing figures.

BRIEF DESCRIPTION OF THE DRAWING FIGURES

[0008] The accompanying drawing figures incorporated in and forming a part of this specification illustrate several aspects of the disclosure, and together with the description serve to explain the principles of the disclosure.

[0009] FIG. **1** illustrates one embodiment of a tunable radio frequency (RF) diplexer, wherein a phase inversion component is provided by an RF filter between a first hybrid coupler and a second hybrid coupler.

[0010] FIG. **2**A illustrates exemplary procedures that may be implemented by the tunable RF diplexer shown in FIG. **1** so that the tunable RF diplexer can provide RF receive diplexing to two different RF receive signals.

[0011] FIG. **2**B illustrates exemplary procedures that may be implemented by the tunable RF diplexer shown in FIG. **1** so that the tunable RF diplexer can provide RF transmission diplexing to two different RF transmission signals.

[0012] FIG. **2**C illustrates two different RF input signals in two different RF communication bands.

[0013] FIG. **2**D illustrates a frequency response of the RF filter circuit shown in FIG. **1**, where the frequency response defines a passband and a stopband.

[0014] FIG. **2**E illustrates the frequency response of the RF filter circuit shown in FIG. **1**, where the passband has been shifted into one of RF communication bands shown in FIG. **2**C, and the stopband has been shifted into the other RF communication band shown in FIG. **2**C.

[0015] FIG. **2**F is another representation of the frequency response shown in FIG. **2**E.

[0016] FIG. **2**G and FIG. **2**H illustrate quadrature hybrid signals generated by splitting the two different RF input signal shown in FIG. **2**C.

[0017] FIG. **3**A illustrates a receive signal flow for one of the RF receive signals described in FIG. **2**A.

[0018] FIG. **3**B illustrates a receive signal flow for the other RF receive signal described in FIG. **2**A.

[0019] FIG. **3**C illustrates a transmission signal flow for one of the RF transmission signals described in FIG. **2**B.

[0020] FIG. **3**D illustrates a transmission signal flow for the other RF transmission signal described in FIG. **2**B

[0021] FIG. **4** illustrates an example of the tunable RF diplexer shown in FIG. **1**, wherein the phase inversion component is provided by weakly coupled resonators within an RF filter path.

[0022] FIG. **5** is a frequency domain representation of S parameters for the tunable RF diplexer shown in FIG. **4**.

[0023] FIG. **6** illustrates another example of the tunable RF diplexer shown in FIG. **4** wherein the phase inversion component is provided by a single-ended transformer in the RF filter circuit.

[0024] FIG. **7** illustrates a frequency domain representation of S parameters for the tunable RF diplexer shown in FIG. **6**.

[0025] FIG. **8** illustrates yet another example of the tunable RF diplexer shown in FIG. **4** wherein the phase inversion component is provided by a differential transformer in the RF filter circuit.

[0026] FIG. **9** illustrates yet another example of the tunable RF diplexer shown in FIG. **4** wherein the phase inversion component is provided by a single-ended to differential transformer in the RF filter circuit.

[0027] FIG. **10** illustrates another embodiment of a tunable RF diplexer, wherein the phase inversion component is provided by a phase shifter configured to provide a positive differential phase shift.

[0028] FIG. **11** illustrates yet another embodiment of a tunable RF diplexer, wherein the phase inversion component is provided by a phase shifter configured to provide a negative differential phase shift.

[0029] FIG. **12** illustrates still another embodiment of the tunable RF diplexer where the phase inversion component is provided by a single-ended to differential transformer connected to the RF filter circuit.

[0030] FIG. **13** illustrates yet another exemplary embodiment of the tunable RF diplexer that is similar to the embodiment in FIG. **4** and where the RF filter circuit is tunable to provide a notch both at a high-frequency side and a low-frequency side of a passband.

[0031] FIG. **14** illustrates a frequency response of the RF filter circuit shown in FIG. **13**.

[0032] FIG. **15** illustrates a frequency domain representation of S parameters for the tunable RF diplexer shown in FIG. **13**.

DETAILED DESCRIPTION

[0033] The embodiments set forth below represent the necessary information to enable those skilled in the art to practice the embodiments and illustrate the best mode of practicing the embodiments. Upon reading the following description in light of the accompanying drawing figures, those skilled in the art will understand the concepts of the disclosure and will recognize applications of these concepts not particularly addressed herein. It should be understood that these concepts and applications fall within the scope of the disclosure and the accompanying claims.

[0034] Note that relational terminology such as "substantially," "approximately," and/or the like, should be interpreted objectively in accordance with the communication device and technological environment in which the radio frequency (RF) diplexer is employed and, in addition, the performance parameters relevant to the operation of the RF diplexer for at least one the particular application of the RF diplexer within the communication device [or at least one prospective communication device] and the technological environment [or at least one prospective technological environment].

[0035] This disclosure describes different embodiments of a tunable RF diplexer and methods of operating the same. Embodiments of the tunable RF diplexer can be used to provide receive diplexing and/or transmission diplexing. To provide diplexing, the tunable RF diplexer includes a first hybrid coupler, a second hybrid coupler, an RF filter circuit, and a phase inversion component. In some embodiments, the phase inversion component may be provided by the first hybrid coupler, the second hybrid coupler, or the RF filter circuit. In other embodiments, the phase inversion component is provided as a separate component. As explained in further detail below, the first hybrid coupler, the second hybrid coupler, or the RF filter circuit is provided to split and route RF signals to and from the appropriate ports in order to provide diplexing. The phase inversion component, however, is configured to provide a differential phase shift of approximately 180 degrees in one of the paths of the tunable RF diplexer. The benefit of introducing the differential phase shift is that it provides increased broadband isolation between the different frequency bands being diplexed by the tunable RF diplexer.

[0036] FIG. **1** illustrates an embodiment of a tunable radio frequency (RF) diplexer **10**. An antenna **12** is operably associated with the tunable RF diplexer **10** and is capable of emitting or radiating RF signals in different RF frequency bands. In order to prevent out-of-band noise and spurious emissions from distorting RF signals in the different RF frequency band, the tunable RF diplexer **10** provides isolation between RF signals as well as out-of-band filtering. Accordingly, the tunable RF diplexer **10** allows for an RF receive input signal **14** and an RF receive input signal **16** to be received simultaneously by the antenna **12**. The RF receive input signal **14** and the RF receive input signal **16** may be provided in different frequency bands.

[0037] The tunable RF diplexer **10** is operable to separate (i.e., split) the RF receive input signal **14** and the RF receive input signal **16** and route them appropriately. In this embodiment, the tunable RF diplexer **10** includes a first hybrid coupler **18**, a second hybrid coupler **20**, an RF filter circuit **22**, and an impedance termination **24**. The first hybrid coupler **18** receives the RF receive input signal **14** and the RF receive input signal **16** from the antenna **12**. An RF receive output signal **26** is provided by the second hybrid coupler **20** and output to downstream circuitry, such as baseband circuitry. The RF receive output signal **26** is essentially the RF receive input signal **14** after the tunable RF diplexer **10** has filtered and routed the RF receive input signal **14**. An RF receive output signal **26** is provided by the second hybrid coupler **20** and output to downstream circuitry, such as baseband circuitry. The RF receive output signal **26** is essentially the RF receive input signal **14** after the tunable RF diplexer **10** has filtered and routed the RF receive input signal **14**. An RF receive output signal **28** is also provided by the second hybrid coupler **20** and output to downstream circuitry, such as baseband circuitry. The RF receive output signal **28** is essentially the RF receive input signal **16** after the tunable RF diplexer **10** has filtered and routed the RF receive input signal **16**.

[0038] The tunable RF diplexer **10** also allows for an RF transmission input signal **30** and an RF transmission input signal **32** to be combined for transmission by the antenna **12** simultaneously. The second hybrid coupler **20** is configured to receive the RF transmission input signal **30**. In response, the first hybrid coupler **18** outputs an RF transmission output signal **34** towards the antenna **12**. The RF transmission output signal **34** is simply the RF transmission input signal **30** after filtering and routing by the tunable RF diplexer **10**. Additionally, the first hybrid coupler **18** is configured to receive the RF transmission input signal **32**. In response, the first hybrid coupler **18** outputs an RF transmission output signal **36** towards the antenna **12**. The RF transmission output signal **36** is simply the RF transmission input signal **32** after filtering and routing by the tunable RF diplexer **10**. The RF transmission input signal **30** and the RF transmission input signal **32** may each be received from upstream circuitry, such as a power amplifier.

[0039] As explained in further detail below, the first hybrid coupler **18**, the RF filter circuit **22**, and the second hybrid coupler **20** provide the appropriate isolation between the RF receive input signals **14**, **16** and the RF frequency bands. The first hybrid coupler **18**, the RF filter circuit **22**, and the second hybrid coupler **20** provide the appropriate isolation between the RF transmission input signals **30**, **32** and the RF frequency bands. The RF filter circuit **22** includes a first RF filter **38**A across its top ports and an second RF filter **38**B across its bottom ports. Thus, the RF filter circuit **22** is a four-port network. However, the first RF filter **38**A and the second RF filter **38**B are independent of one another and each of the RF filters **38**A, **38**B operates as a two-port network. Also, the first RF filter **38**A and the second RF filter **38**B may be identical, and thus may each have the same individual frequency response. In this embodiment, the first RF filter **38**A is a RF bandpass filter that defines a transfer response with a passband. The passband is symmetrical in that it is the same in both directions of propagation across the first RF filter **38**A to and from the first hybrid coupler **18** and the second hybrid coupler **20**. The second RF filter **38**B is another RF bandpass filter that defines a transfer response with a passband. The passband is also symmetrical in that it is the same in both directions of propagation across the second RF filter **38**B to and from the first hybrid coupler **18** and the second hybrid coupler **20**. In this case, the passband of the first RF filter **38**A and the passband of the second RF filter **38**B are identical. As explained in further detail below, the second RF filter **38**B includes the phase inversion component.

[0040] Referring now to FIGS. **2**A and **2**B, FIG. **2**A illustrates exemplary procedures that may be implemented to provide RF diplexing with respect to receiving the RF receive input signal **14** and the RF receive input signal **16** at the antenna **12**. FIG. **2**B illustrates exemplary procedures that may be implemented to provide RF diplexing with respect to transmitting the RF transmission output signal **34** and the RF transmission output signal **36** from the antenna. As explained in further detail below, the procedures described in FIG. **2** are implemented by the tunable RF diplexer **10** shown in FIG. **1**. Different embodiments of these exemplary procedures may be implemented depending on a particular component structure of a tunable RF diplexer **10**. Furthermore, the order in which the procedures are presented is not intended to imply a required sequence for the procedures. Rather, the procedures may be implemented in a different sequence and/or some or all of the procedures may be implemented simultaneously.

[0041] As shown in FIG. **2**A, the tunable RF diplexer **10** (shown in FIG. **1**) receives the RF receive input signal **14** (procedure **1000**). The RF receive input signal **14** was initially intercepted by the antenna **12** (shown in FIG. **1**). Additionally, the tunable RF diplexer **10** receives the RF receive input signal **16** with the first hybrid coupler **18** (procedure **1002**). The RF receive input signal **16** was also initially intercepted by the antenna **12**. In one embodiment, the tunable RF diplexer **10** is configured to provide diplexing when the RF receive input signal **14** is provided within an industrial, scientific, and medical (ISM) frequency band having a frequency range between 2.4 GHz and 2.5 GHz and a center frequency of around 2.450 GHz. Thus, the RF receive output signal **26** is also found in the same ISM frequency band. The RF receive input signal **16** can be provided within any one of multiple Medium Band (MB) and High Band (HB) frequency bands. For example, the RF receive input signal **16** can be provided in B1-B7 frequency bands which extend between 1.810 GHz to 2.690 GHz. The RF receive output signal **28** is thus provided in the same MB/HB frequency band.

[0042] With respect to FIG. **2**B, the tunable RF diplexer **10** receives the RF transmission input signal **30** with the second hybrid coupler **20** (procedure **2000**). The RF transmission input signal **30** was initially received from upstream circuitry (e.g., a power amplifier) by the second hybrid coupler **20**. Additionally, the tunable RF diplexer **10** receives the RF transmission input signal **32** (procedure **2002**). The RF transmission input signal **32** was initially received from upstream circuitry (e.g., a power amplifier) by the second hybrid coupler **20**. In one embodiment, the tunable RF diplexer **10** is configured to provide diplexing when the RF transmission input signal **30** is provided within the same ISM frequency band as the RF receive input signal **14**. Thus, the RF transmission output signal **34** is also provided in the same ISM frequency band. The RF transmission input signal **32** can be provided within any one of multiple MB and HB frequency bands. For example, the RF transmission input signal **32** can be provided in B1-B7 frequency bands which extend between 1.810 GHz to 2.690 GHz. The RF transmission output signal **36** is thus provided in the same corresponding frequency band as the RF transmission input signal **32**.

[0043] Accordingly, the tunable RF diplexer **10** provides diplexing so that RF signals in different ISM and MB/HB frequency bands can share the antenna **12**. In addition, the tunable RF diplexer **10** is configured to allow for carrier aggregation and combine the RF transmission output signals **34**, **36** in the separate ISM and Cellular MB/HB frequency bands to emit the RF transmission output signals **34**, **36** are simultaneously emitted by the antenna **12**. Again, to operate optimally, the tunable RF diplexer **10** is required to provide isolation across broadband frequency ranges from 1810 MHz to 2690 MHz. The use of tunable of ISM/MB-HB cellular diplexer provides other benefits, for example, when operating into cellular mode only, the ISM bandpass filter is retuned out of the ISM band frequency into either a lower frequency or higher frequency to reduce the IL of the operating cellular frequency as shown in FIG. **23**.

[0044] FIG. **2**C illustrates a graph of one embodiment of an RF input signal **40** and an RF input signal **42** in the frequency domain. With respect to the procedures described in FIG. **2**A, the RF input signal **40** is the RF receive input signal **14**, and the RF input signal **42** is the RF receive input signal **16**. However, with respect to the procedures described in FIG. **2**B, the RF input signal **40** is the RF transmission input signal **30**, and the RF input signal **42** is the RF transmission input signal **32**. The RF input signal **40** operates in an RF communication band **44**, which is one embodiment of the ISM frequency band. In this embodiment, the RF communication band **44** is the set of frequencies between a cutoff frequency C1 and a cutoff frequency C2. Note that the RF communication band **44** may include additional RF subbands, such as the RF subband **46**. The RF subband **46** may be a transmission subband, a receive subband, and/or the like. The RF subband **46** is defined as the set of frequencies between a cutoff frequency f_{B1} and a cutoff frequency f_{B2}. With respect to the RF input signal **42**, the RF input signal **42** operates in an RF communication band **48**, which is one embodiment of the MB/HB frequency bands. In this embodiment, the RF communication band **48** is the set of frequencies between a cutoff frequency C3 and a cutoff frequency C4. Note that the RF communication band **48** may include additional RF subbands, such as the RF subband **50**. The RF subband **50** may be a transmission subband, a receive subband, and/or the like.

The RF subband **50** is defined as the set of frequencies between a cutoff frequency f_{Y1} and a cutoff frequency f_{Y2}.

[0045] In this example, a signal bandwidth **52** of the RF input signal **40** is the set of frequencies that corresponds to the portion of the RF input signal **40** within 3 dB of a maximum magnitude **54**. The RF input signal **40** shown in FIG. **2**C operates at a frequency f_A. This frequency f_A corresponds to the maximum magnitude **54** of the RF input signal **40**. For example, the frequency f_A may be a carrier frequency of the RF input signal **40**. The signal bandwidth **52** reaches a cutoff frequency f_{A1}, since the frequency f_{A1} corresponds to a value of the RF input signal **40** that is 3 dB from the maximum magnitude **54**. The signal bandwidth **52** reaches a cutoff frequency f_{A2}, because the cutoff frequency f_{A2} corresponds to a value of the RF input signal **40** that is 3 dB from the maximum magnitude **54**.

[0046] Also, in this example, a signal bandwidth **56** of the RF input signal **42** is the set of frequencies that corresponds to the portion of the RF input signal **42** within 3 dB of a maximum magnitude **58**. The RF input signal **42** shown in FIG. **2**A operates at a frequency f_Z. This frequency f_Z corresponds to the maximum magnitude **58** of the RF input signal **42**. For example, the frequency f_Z may be a carrier frequency of the RF input signal **42**. The signal bandwidth **56** reaches a cutoff frequency f_{Z1}, since the frequency f_{Z1} corresponds to a value of the RF input signal **42** that is 3 dB from the maximum magnitude **58**. The signal bandwidth **56** reaches a cutoff frequency f_{Z2}, because the cutoff frequency f_{Z2} corresponds to a value of the RF input signal **42** that is 3 dB from the maximum magnitude **58**.

[0047] Portions of the RF input signal **40** and the RF input signal **42** outside of their respective signal bandwidths **52**, **56** may be considered spurious emissions. In other words, the portions of the RF input signal **40** and the RF input signal **42** may be reduced or eliminated without affecting the corresponding information or data in the RF input signal **40** and the RF input signal **42**. Spurious emissions include parasitic emissions, intermodulation, interference, harmonic emissions, and frequency conversion products. The signal bandwidth **52** and the signal bandwidth **56** are defined as 3 dB bandwidths for pragmatic purposes. Generally speaking, at least for the types of signals being shown in FIG. **2**C, the signal bandwidths **52**, **56** are measured by finding 3 dB magnitudes from the maximum magnitudes **54**, **58**, as explained above. However, more accurately, a necessary signal bandwidth is an exact amount of signal bandwidth required to carry the information or data of a signal. Anything outside of this necessary bandwidth would be considered spurious emissions. Thus, the signal bandwidth **52** and the signal bandwidth **56** may or may not include a small portion of the spurious emissions. The necessary signal bandwidths may be slightly smaller or slightly greater than the signal bandwidths **52** and **56**.

[0048] Finally, it should be noted that the RF input signal **40** and the RF input signal **42** may each be narrow-band signals. Accordingly, the RF input signal **40** and the RF input signal **42** may represent time division multiplexing (TDM) signals, frequency division multiplexing (FDM) signals, space division multiplexing (SDM) signals, and/or the like. Accordingly, these narrow-band signals may be said to operate at a particular frequency, which for the RF input signal **40** is the frequency f_A and for the RF input signal **42** is the frequency f_Z. The RF subband **46** is thus an RF channel within the RF communication band **44**, while the RF subband **50** is an RF channel within the RF communication band **48**.

[0049] However, this disclosure is not limited to narrow-band signals and the examples given in FIG. **2**C and throughout this disclosure are not intended to be limited in this manner. Rather, embodiments of the tunable RF diplexer **10** and the method shown in FIGS. **2**A and **2**B may be provided for wide-band signals, and also for both wide-band and narrow-band signals. With wide-band signals, such as orthogonal frequency division multiple access (OFDMA) signals or Code Division Multiple Access (CDMA) signals, information or data is coded and spread across a larger portion of the spectrum. Thus, there would be no signal with a single carrier frequency that has all of the information or data, but rather there may be various carriers carrying different coded portions of the information. As such, the RF communication band **44** and/or the RF communication band **48** may include various RF channels. Similarly, the RF communication band **48** may include various RF channels. With CDMA signals and other wide-band spectrum signals, it is more practical to define the bandwidths by simply using the necessary bandwidth, as is known in the art.

[0050] FIG. **2**D illustrates one embodiment of a frequency response **60** provided by the RF filter circuit **22**. In FIG. **2**D, the frequency response **60** represents S21 and S12 parameters of each of the RF filters **38**A, **38**B (shown in FIG. **1**) individually, as a function of frequency. Thus, the two-port S21 and S12 parameter of the first RF filter **38**A is represented by the frequency response **60** in FIG. **2**D. Since the second RF filter **38**B is identical to the first RF filter **38**A, the two-port S21 and S12 parameter of the second RF filter **38**B is also represented by the frequency response **60** in FIG. **2**D. The two-port S21 and S12 parameter represents the forward and reverse transmission of the RF filters **38**A, **38**B, as a function of frequency. A passband **62** corresponds to S21/S12 values in the frequency response **60** that are within 3 dB of a maxima **64**. A stopband **66** is determined relative to a minima **68**. The maxima **64** and the minima **68** are set by the poles and zeros of the frequency response **60**. The stopband **66** is a set of frequencies that correspond to S21/S12 values within 3 dB of the minima **68**. In this embodiment, the frequency response **60** defines the stopband **66** as a notch. As explained in further detail below, the RF filter circuit **22** is tunable so as to shift the passband **62** and the stopband **66**. Thus, by tuning the RF filter circuit **22**, the frequency response **60** may be transposed, so that the passband **62** and the stopband **66** are provided at the desired frequency bands.

[0051] Referring now to FIGS. **2**A, **2**B, and **2**E, FIG. **2**E illustrates the frequency response **60** of the RF filter circuit **22** once the passband **62** is shifted to include the RF communication band **44**, and once the stopband **66** is shifted to include the RF communication band **48**. The tuning circuit **69** (shown in FIG. **1**) tunes the passband **62** so that the passband **62** includes the RF communication band **44**. The tuning circuit **69** may also tune the stopband **66** so that the stopband **66** includes the RF communication band **48**. In this manner, signals that operate in the RF communication band **44** are passed by the RF filter circuit **22**, while signals that operate in the RF communication band **48** are blocked by the RF filter circuit **22**.

[0052] Referring now to FIGS. **2**A, **2**B, and **2**F, FIG. **2**F also illustrates the frequency response **60** of the RF filter circuit **22** once the passband **62** is shifted to include the RF communication band **44**, and once the stopband **66** is shifted to include the RF communication band **48**. However, in FIG. **2**F, the frequency response **60** represents S11 and S22 parameters of each of the RF filters **38**A, **38**B (shown in FIG. **1**) individually, as a function of frequency. Thus, the two-port S11 and S22 parameter of the first RF filter **38**A is represented by the frequency response **60** in FIG. **2**F. Since the second RF filter **38**B is identical to the first RF filter **38**A, the two-port S11 and S22 parameter of the second RF filter **38**B is also represented by the frequency response **60** in FIG. **2**F. The two-port S11 and S22 parameter represents the forward and reverse return loss of the RF filters **38**A, **38**B, as a function of frequency. Note that in this embodiment, the S11/S22 values of the stopband **66** are at or near zero (0) dB in the RF communication band **48**. By placing the stopband **66** at or near zero (0) dB, reflections in the stopband **66** are maximized, while the insertion losses within the RF communication band **48** are minimized. Filtering thus removes noise outside of the RF communication band **48** while minimizing losses of reflected signals.

[0053] Referring now to FIGS. **2**G and **2**H, the tunable RF diplexer **10** is configured to split the RF input signal **40** into a first RF quadrature hybrid signal (QHS) **70** and a second RF QHS **72**. As such, the first RF QHS **70** is 90 degrees or π/2 radians out of phase with the second RF QHS **72**. Also, the tunable RF diplexer **10** is configured to split the RF input signal **42** into a first RF QHS **74** and a second RF QHS **76**. FIGS. **2**G and **2**H illustrate the first RF QHS **70** (shown in FIG. **2**G) and the second RF QHS **72** (shown in FIG. **2**H) generated by splitting the RF input signal **40**. The first RF QHS **70** and the second RF QHS **72** have substantially identical magnitude characteristics as the RF input signal **40**. However, both the first RF QHS **70** and the second RF QHS **72** have a power spectral density that is at a power ratio of the power spectral density of the RF input signal **40**. In this example, the power ratio is 3 dB, and thus the first RF QHS **70** and the second RF QHS **72** have approximately one half of the power of the RF input signal **40**. The first RF QHS **70** and the second RF QHS **72** are quadrature hybrids, since there is approximately a 90-degree or π/2 radians phase difference between the signals.

[0054] Of course, non-ideal characteristics of the tunable RF diplexer **10**, such as parasitic impedances, may result in the first RF QHS **70** and the second RF QHS **72** being slightly unbalanced with respect to one another, or having slightly less than half the power of the RF input signal **40**. Also, non-ideal characteristics can result in the phase difference between the first RF QHS **70** and the second RF QHS **72** fluctuating somewhat from a 90-degree or π/2 radians phase difference. These types of errors are acceptable so long as the first RF QHS **70** and the second RF QHS **72** can be generated to comply with spectrum requirements for the RF communication standard with respect to the RF input signal **40**. As explained in further detail below, the tunable RF diplexer **10** is configured to provide a differential phase shift to the second RF QHS **72** after the RF input signal **40** has been split. The differential phase shift is approximately 180 degrees or π radians. In this embodiment, the second RF filter **38**B (shown in FIG. **1**) is configured to provide the differential phase shift and includes the phase inversion component that provides the differential phase shift. With regard to the ISM frequency band and MB/HB frequency band embodiment, IM3 cancellation is provided by the architecture of the back-to-back hybrid couplers, **20**.

[0055] With respect to the procedures in FIG. **2**A, the RF input signal **40** is the RF receive input signal **14**, shown in FIG. **1**. Accordingly, the first hybrid coupler **18** is configured to split the RF receive input signal **14** into a first RF quadrature hybrid receive signal (QHRS) (which in the procedures of FIG. **2**A is the first RF QHS **70** shown in FIG. **2**G) and a second RF QHRS (which in the procedures of FIG. **2**A is the second RF QHS **72** shown in FIG. **2**H) (procedure **1004**). As such, the first RF QHRS is 90 degrees or π/2 radians out of phase with the second RF QHRS when the first hybrid coupler **18** splits the RF receive input signal **14**. The RF filter circuit **22** then filters the first RF QHRS and the second RF QHRS. More specifically, the second RF filter **38**B provides the differential phase shift to the second RF QHRS (procedure **1006**), and the RF filter circuit **22** passes the first RF QHRS and the second RF QHRS to the second hybrid coupler **20** (procedure **1008**). As explained in further detail below, the differential phase shift may be provided by other phase inversion components, such as phase shifter, transformers, and the like. The second hybrid coupler **20** provides a quadrature phase shift (approximately 90-degree or π/2 radians phase shift) to the second RF QHRS (procedure **1010**). In this manner, the second hybrid coupler **20** combines the first RF QHRS and the second RF QHRS into the RF receive output signal **26** (procedure **1012**). These procedures are further explained in Figures below.

[0056] With respect to the procedures in FIG. **2**B, the RF input signal **40** is the RF transmission input signal **30**, shown in FIG. **1**. Accordingly, the second hybrid coupler **20** is configured to split the RF transmission input signal **30** into a first RF quadrature hybrid transmission signal (QHTS) (which in the procedures of FIG. **2**B is the first RF QHS **70** shown in FIG. **2**G) and a second RF QHTS (which in the procedures of FIG. **2**B is the second RF QHS **72** shown in FIG. **2**H) (procedure **2004**). As such, the first RF QHTS is 90 degrees or π/2 radians out of phase with the second RF QHTS. The RF filter circuit **22** then filters the first RF QHTS and the second RF QHTS. More specifically, the second RF filter **38**B provides the differential phase shift to the second RF QHTS (procedure **2006**), and the RF filter circuit **22** passes the first RF QHTS and the second RF QHTS to the first hybrid coupler **18** (procedure **2008**). The first hybrid coupler **18** provides a quadrature phase shift (approximately 90-degree or π/2 radian phase shift) to the second RF QHTS (procedure **2010**). In this manner, the first hybrid coupler **18** also combines the first RF QHTS and the second RF QHTS into the RF transmission output signal **34** (procedure **2012**).

[0057] Referring again to FIGS. **2**G and **2**H, the tunable RF diplexer **10** is also configured to split the RF input signal **42** into the first RF QHS **74** and the second RF QHS **76**, as mentioned above. As such, the first RF QHS **74** is 90 degrees or π/2 radians out of phase with the second RF QHS **76**. FIGS. **2**G and **2**H illustrate the first RF QHS **74** (shown in FIG. **2**G) and the second RF QHS **76** (shown in FIG. **2**H) generated by splitting the RF input signal **42**. The first RF QHS **74** and the second RF QHS **76** have substantially identical magnitude characteristics as the RF input signal **42**. However, both the first RF QHS **74** and the second RF QHS **76** have a power spectral density that is at a power ratio of the power spectral density of the RF input signal **42**. In this example, the power ratio is 3 dB, and thus the first RF QHS **74** and the second RF QHS **76** have approximately one half of the power of the RF input signal **42**. The first RF QHS **74** and the second RF QHS

76 are quadrature hybrids, since there is approximately a 90-degree or $\pi/2$ radians phase difference between the signals.

[0058] Of course, non-ideal characteristics of the tunable RF diplexer **10**, such as parasitic impedances, may result in the first RF QHS **74** and the second RF QHS **76** being slightly unbalanced with respect to one another, or having slightly less than half the power of the RF input signal **42**. Also, non-ideal characteristics can result in the phase difference between the first RF QHS **74** and the second RF QHS **76** fluctuating somewhat from a 90-degree or $\pi/2$ radians phase difference. These types of errors are acceptable so long as the first RF QHS **74** and the second RF QHS **76** can be generated to comply with spectrum requirements for the RF communication standard with respect to the RF input signal **42**. As explained in further detail below, the tunable RF diplexer **10** is configured to provide a differential phase shift to either the first RF QHS **74** or the second RF QHS **76** after the RF input signal **42** has been split. The differential phase shift is approximately 180 degrees or π radians. As mentioned above, in this embodiment, the second RF filter **38**B (shown in FIG. **1**) is configured to provide the differential phase shift.

[0059] With respect to the procedures in FIG. **2**A, the RF input signal **42** is the RF receive input signal **16**, shown in FIG. **1**. Accordingly, the first hybrid coupler **18** is configured to split the RF receive input signal **16** into a first RF QHRS (which in the procedures of FIG. **2**A is the first RF QHS **74** shown in FIG. **2**G) and a second RF QHRS (which in the procedures of FIG. **2**A is the second RF QHS **76** shown in FIG. **2**H) (procedure **1014**). As such, the first RF QHRS is 90 degrees or $\pi/2$ radians out of phase with the second RF QHRS. The RF filter circuit **22** then filters the first RF QHRS and the second RF QHRS. More specifically, the RF filter circuit **22** blocks the first RF QHRS and the second RF QHRS so that the first RF QHRS and the second RF QHRS is reflected back toward the first hybrid coupler **18** (procedure **1016**). The first hybrid coupler **18** then provides a quadrature phase shift (approximately 90-degree or $\pi/2$ radians phase shift) to the first RF QHRS (procedure **1018**). In this manner, the first hybrid coupler **18** combines the first RF QHRS and the second RF QHRS generated by splitting the RF input signal **42** into the RF receive output signal **28** (procedure **1020**). These procedures are further explained in Figures below. Furthermore, note that the procedures **1000**, **1004-1012** may all occur simultaneously with procedures **1002**, **1014-1020**.

[0060] With respect to the procedures in FIG. **2**B, the RF input signal **42** is the RF transmission input signal **32**, shown in FIG. **1**. Accordingly, the first hybrid coupler **18** is configured to split the RF transmission input signal **32** into a first RF QHTS (which in the procedures of FIG. **2**B is the first RF QHS **74** shown in FIG. **2**G) and a second RF QHTS (which in the procedures of FIG. **2**B is the second RF QHS **76** shown in FIG. **2**H) (procedure **2014**). As such, the first RF QHTS is 90 degrees or $\pi/2$ radians out of phase with the second RF QHTS. The RF filter circuit **22** then filters the first RF QHTS and the second RF QHTS generated by splitting the RF transmission input signal **32**. More specifically, the RF filter circuit **22** blocks the first RF QHTS and the second RF QHTS generated by splitting the RF transmission input signal **32** so that the first RF QHTS and the second RF QHTS generated by splitting the RF transmission input signal **32** are reflected back to the first hybrid coupler **18** (procedure **2016**). The first hybrid coupler **18** then provides a quadrature phase shift (approximately 90-degree or $\pi/2$ radians phase shift) to the first RF QHTS (procedure **2018**). In this manner, the first hybrid coupler **18** combines the first RF QHTS and the second RF QHTS generated by splitting the RF transmission input signal **32** into the RF transmission output signal **36** (procedure **2020**). These procedures are further explained in Figures below. Furthermore, note that the procedures **2000**, **2004-2012** may all occur simultaneously with procedures **2002**, **2014-2020**.

[0061] Referring again to FIGS. **2**G and **2**H, since the RF input signal **40** is split into the first RF QHS **70** and the second RF QHS **72**, both the first RF QHS **70** and the second RF QHS **72** operate in the RF communication band **44**. When the hybrid couplers **18**, **20** output the first RF QHS **70** and the second RF QHS **72**, the RF filter circuit **22** filters the first RF QHS **70** and the second RF QHS **72** to pass the first RF QHS **70** and the second RF QHS **72** within the passband **62**. As shown in FIGS. **2**G and **2**H, the frequency response **60** of the RF filter circuit **22** has been transposed so that the passband **62** and the stopband **66** are shifted into the RF communication band **44**. More particularly, the passband **62** is shifted so that the RF communication band **44** is in the passband **62**.

[0062] The stopband **66** has been shifted so that the RF communication band **48** is in the stopband **66**. Since the first RF QHS **70** and the second RF QHS **72** are within the passband **62**, the RF filter circuit **22** is configured to pass the first RF QHS **70** and the second RF QHS **72**. However, the RF filter circuit **22** filters the first RF QHS **74** and the second RF QHS **76** to reflect the first RF QHS **74** and the second RF QHS **76** within the stopband **66**. The first RF QHS **74** and the second RF QHS **76** operate within the RF communication band **48**. Since the stopband **66** is in the RF communication band **48**, the RF filter circuit **22** has been tuned to block the first RF QHS **74** and the second RF QHS **76**.

[0063] As shown in FIGS. **2**G and **2**H, the first RF QHS **70** has a signal bandwidth **78**, and the second RF QHS **72** has a signal bandwidth **80**. Although the first RF QHS **70** and the second RF QHS **72** have approximately half the spectral power density (excluding losses) of the RF input signal **40** shown in FIG. **2**C, the signal bandwidth **78** of the first RF QHS **70** and the signal bandwidth **80** of the second RF QHS **72** have approximately the same size and are located at approximately the same frequencies. In FIGS. **2**E and **2**F, the signal bandwidth **78** of the first RF QHS **70** and the signal bandwidth **80** of the second RF QHS **72** are between the frequencies f_{A1} and f_{A2}. However, non-ideal circuit behavior may result in either slight misalignments and/or slight size differences in the signal bandwidth **78** and the signal bandwidth **80**. The amount of error that is permissible may depend on the particular application and spectrum requirements. The tuning circuit **69** is configured to tune the frequency response **60** of the RF filter circuit **22** so that the signal bandwidth **78** of the first RF QHS **70** and the signal bandwidth **80** of the second RF QHS **72** are each within the passband **62**. Thus, the RF filter circuit **22** filters the first RF QHS **70** and the second RF QHS **72** to pass the first RF QHS **70** and the second RF QHS **72** within the passband **62** to the second hybrid coupler **20**.

[0064] As shown in FIGS. **2**G and **2**H, the first RF QHS **74** has a signal bandwidth **82**, while the second RF QHS **76** has a signal bandwidth **84**. Although the first RF QHS **74** and the second RF QHS **76** have approximately half the power spectral density of the RF input signal **42** (excluding losses) shown in FIG. **2**C. The signal bandwidth **82** of the first RF QHS **74** and the signal bandwidth **84** of the second RF QHS **76** are configured to be approximately the same as the signal bandwidth **82** of the RF input signal **42**. In the embodiments illustrated in FIGS. **2**G and **2**H, the signal bandwidth **82** and the signal bandwidth **84** are both between the frequencies f_{Z1} and f_{Z2}. However, non-ideal circuit behavior may result in slight misalignments or size differences in the signal bandwidth **82** and the signal bandwidth **84**. The amount of error that is permissible may depend on the particular application and spectrum requirements. The tuning circuit **69** is configured to tune the frequency response **60** of the RF filter circuit **22** so that the signal bandwidth **82** of the first RF QHS **74** and the signal bandwidth **84** of the second RF QHS **76** are each within the stopband **66**. In this manner, the RF filter circuit **22** blocks the first RF QHS **74** and the second RF QHS **76** such that the first RF QHS **74** and the second RF QHS **76** are reflected back to the second hybrid coupler **20**.

[0065] FIG. **3**A illustrates the tunable RF diplexer **10** along with a receive signal flow of the tunable RF diplexer **10** with respect to the procedures **1000**, **1004-1012** for the RF receive input signal **14** and the RF receive output signal **26**. As shown in FIG. **3**A, the first hybrid coupler **18** has a first port **86**, a second port **88**, a third port **90**, and a fourth port **92**, while the second hybrid coupler **20** has a fifth port **94**, a sixth port **96**, a seventh port **98**, and an eighth port **100**.

[0066] The antenna **12** intercepts the RF receive input signal **14** as electromagnetic waves in free space. These electromagnetic waves result in excitations within the antenna **12**, thereby converting the electromagnetic waves into the RF receive input signal **14**. The first hybrid coupler **18** is operable to receive the RF receive input signal **14**. In this particular embodiment, the first hybrid coupler **18** is coupled to receive the RF receive input signal **14** at the first port **86** from the antenna **12**. The first hybrid coupler **18** is operable to split the RF receive input signal **14** into a first RF QHRS **102** and the second RF QHRS **104**. In this manner, the first RF QHRS **102** and the second RF QHRS **104** have approximately the same power ratio with respect to the RF receive input signal **14**, but have a quadrature phase difference of approximately 90 degrees or π/2 radians with respect to one another.

[0067] With regard to the first hybrid coupler **18** shown in FIG. **3**A, the first port **86** is phase-aligned with the third port **90**, while the first port **86** has a quadrature phase shift with respect to the fourth port **92**. Thus, the first RF QHRS **102** at the third port **90** is approximately phase-aligned with the RF receive input signal **14** at the first port **86**, but there is a quadrature phase difference between the RF receive input signal **14** at the first port **86** and the second RF QHRS **104** at the fourth port **92**.

[0068] Note that in alternative embodiments, this may or may not be the case. For example, there may be a phase shift between the first port **86** and the third port **90** (such as +45 degrees or +π/4 radians). The phase shift between the first port **86** and the fourth port **92** may then be equal to this phase shift plus or minus 90 degrees (such as +135 degrees or +3π/4 radians, −45 degrees or −π/4 radians). Accordingly, so long as the phase difference between the first RF QHRS **102** and the second RF QHRS **104** is about 90 degrees or π/2 radians, phase alignment between the third port **90** and the first port **86**, and between the fourth port **92** and the first port **86**, can vary. The first RF QHRS **102** is output at the third port **90** toward the first RF filter **38**A of the RF filter circuit **22**. The first RF filter **38**A is connected between the third port **90** and the fifth port **94**. Additionally, the second RF QHRS **104** is output at the fourth port **92** toward the second RF filter **38**B of the RF filter circuit **22**. The second RF filter **38**B is connected between the fourth port **92** and the sixth port **96**.

[0069] The tunable RF diplexer **10** includes a phase inversion component that is connected between the first hybrid coupler **18** and the second hybrid coupler **20**. The phase inversion component is configured to provide a differential phase shift to the second RF QHRS **104**. In this embodiment, the phase inversion component is the second RF filter **38**B in the RF filter circuit **22**. As such, the second RF filter **38**B shown in FIG. **3**A is configured to provide the differential phase shift (i.e. approximately 180 degree/π radian phase shift) to the second RF QHRS **104**. However, as explained in further detail below, the phase inversion component may be provided by any phase inversion component capable of providing a differential phase shift, such as a phase shifter, a transformer, and/or the like. The benefit of introducing the differential phase shift is that it provides increased isolation between diplexed RF communication bands over a greater frequency range. For example, if the RF receive input signal **14** and the RF receive output signal **26** are provided in the ISM frequency band, and the RF receive input signal **16** (shown in FIG. **1**) and the RF receive output signal **28** (shown in FIG. **1**) are provided an MB/HB frequency band, the cancellation of the RF receive input signal **16** (shown in FIG. **1**) and the RF receive output signal **28** (shown in FIG. **1**) is provided through the differential phase shift, rather than simply on a precise power split. This differential phase shift is much easier to maintain over a broad frequency range.

[0070] Referring again to FIG. **3**A, the tuning circuit **69** is configured to tune the frequency response of the RF filter circuit **22** so that the passband **62** of the first RF filter **38**A and the passband **62** of the second RF filter **38**B includes the RF communication band of the RF receive input signal **14** and the RF receive output signal **26**. In this manner, the RF filter circuit **22** is operable to pass the first RF QHRS **102** and the second RF QHRS **104** to the second hybrid coupler **20**. The manner of tuning the frequency response may depend on the topology of the RF filter circuit **22**. For example, the first RF filter **38**A and the second RF filter **38**B shown in FIG. **3**A may both be variable passive filters. Accordingly, one or more reactive impedance components (inductive, capacitive, or both) in each of the first and second RF filters **38**A, **38**B may have a variable reactive impedance level. By varying these variable reactive impedance levels, the poles and zeros of the individual frequency responses provided by each of the first and second RF filters **38**A, **38**B are adjusted. This thereby shifts the passband **62** in the frequency domain. As explained in further detail below, the first and second RF filters **38**A, **38**B may include weakly coupled resonators to provide filtering and the differential phase shift.

[0071] In this embodiment, the tuning circuit **69** illustrated in FIG. **3**A generates a passband tuning control output **106** and a stopband tuning control output **108**. The variable reactive impedance components in both the first RF filter **38**A and the second RF filter **38**B are set in accordance with one or more signal levels of the passband tuning control output **106**. In this manner, the stopband **66** is shifted to include the RF transmission band in accordance with one or more signal levels of the stopband tuning control output **108**. Similarly, reactive impedance levels of variable reactive components in the first RF filter **38**A and the second RF filter **38**B are set in accordance with one or more signal levels of the passband tuning control output **106**. The RF filter circuit **22** may also include active RF filters, Surface Acoustic Wave (SAW) filters, or any other type of RF filter or combination of RF filters that is suitable to provide a desired frequency response. As such, the tuning circuit **69** may employ various types of tuning topologies, depending on the particular filtering topology being employed by the RF filter circuit **22**.

[0072] By placing the passband **62** of the first RF filter **38**A and the second RF filter **38**B in the RF communication band, the RF filter circuit **22** passes the first RF QHRS **102** and the second RF QHRS **104** to the second hybrid coupler **20**. Due to the differential phase shift provided by the second RF filter **38**B, the second RF QHRS **104** has an approximately 270 degree or 3/2π radian phase difference with respect to the first RF QHRS **102** once the first RF QHRS **102** and the second RF QHRS **104** are output from the RF filter circuit **22**.

[0073] Referring again to FIG. **3**A, the second hybrid coupler **20** receives the first RF QHRS **102** from the first RF filter **38**A at the fifth port **94**. The second RF QHRS **104** is received by the second hybrid coupler **20** from the second RF filter **38**B at the sixth port **96**. As discussed above, the phase difference between the first RF QHRS **102** and the second RF QHRS **104** have about 270 degrees or 3π/2 radians. Thus, for example, if the first RF QHRS **102** has a phase of zero degrees, the second RF QHRS **104** would have a phase of approximately 270 degrees (or 3π/2 radians). From the fifth port **94** to the seventh port **98**, the second hybrid coupler **20** provides no phase shift. Alternatively, the second hybrid coupler **20** may be configured to provide a phase shift from the fifth port **94** to the seventh port **98** of Δ (i.e., such as +45 degrees or π/4 radians).

[0074] The second hybrid coupler **20** is configured to output the RF receive output signal **26** from the seventh port **98** in response to the first RF QHRS **102** being received from the RF filter circuit **22** at the fifth port **94** and the second RF QHRS **104** being received from the RF filter circuit **22** at the sixth port **96**. In this particular embodiment, the second hybrid coupler **20** is configured to pass the second RF QHRS **104** from the sixth port **96** to the seventh port **98** by providing another quadrature phase shift. Thus, as seen at the seventh port **98**, the second RF QHRS **104** has a phase of 360 degree or 2π radian phase. The second hybrid coupler **20** provides no phase shift to the first RF QHRS **102** from the sixth port **96** to the seventh port **98**. The first RF QHRS **102** is thus passed with a phase of 0 degrees to the seventh port **98**. Thus, the interference between the first RF QHRS **102** and the second RF QHRS **104** at the seventh port **98** is constructive. Accordingly, the second hybrid coupler **20** is configured to combine the first RF QHRS **102** and the second RF QHRS **104** into the RF receive output signal **26**. The RF receive output signal **26** is then transmitted to external circuitry in an RF front end, such as an RF receive chain.

[0075] The second hybrid coupler **20** shown in FIG. **3**A is configured to provide a quadrature phase shift from the fifth port **94** to the eighth port **100**. In this example, the phase shift is 90 degrees (or π/2 radians), and thus the second RF QHRS **104** has a phase, as seen from the eighth port **100**, of 90 degrees (note that the first RF QHRS **102** was received at the fifth port **94** with a phase of 0 degrees in this example). The second RF QHRS **104** is received with a phase of 270 degrees at the sixth port **96** and the second hybrid coupler **20** provides no phase shift between the sixth port **96** and the eighth port **100**. Thus, the phase difference between the first RF QHRS **102** and the second RF QHRS **104** as seen from the eighth port **100** is about 180 degrees. Accordingly, the quadrature phase shift at the eighth port **100** from the fifth port **94** results in destructive interference between the first RF QHRS **102** and the second RF QHRS **104** at the eighth port **100**. As a result, the first RF QHRS **102** and the second RF QHRS **104** are substantially cancelled at the eighth port **100**. In this manner, the eighth port **100** is substantially isolated from receive signal flow.

[0076] An impedance termination **24** is coupled to the eighth port **100** of the second hybrid coupler **20**. The impedance termination **24** may be a 50 Ohm load. Due to the phase-shifting provided by the first hybrid coupler **18**, the first RF filter **38**A and the second hybrid coupler **20**, spurious emissions from the second port **88** of the first hybrid coupler **18** would see a very high (theoretically infinite) impedance at the seventh port **98** of the second hybrid coupler **20** but only the impedance termination **24** at the eighth port **100**. Thus, the spurious emissions are aggregated to be an aggregated noise signal **110** at the eighth port **100**. This aggregated noise signal **110** is dissipated by the impedance termination **24**. Additionally, the eighth port **100** is isolated from the seventh port **98**. As such, the seventh port **98** is substantially unresponsive to signals incident at the eighth port **100**, and the seventh port **98** is substantially unresponsive to signals incident at the eighth port **100**. An impedance of the impedance termination **24** can be varied by the tuning circuit **69** in order to maintain the impedance termination **24** at a characteristic 50 Ohms.

[0077] FIG. **3**B illustrates the tunable RF diplexer **10** along with the receive signal flow of the tunable RF diplexer **10** with respect to the procedures **1002**, **1014**-**1020** shown in FIG. **2**A for the RF receive input signal **16** and the RF receive output signal **28**. The procedures **1000**, **1004**-**1012** and the procedures for the RF receive input signal **14** and the RF receive output signal **26** shown in FIG. **2**A and illustrated in FIG. **3**A can performed simultaneously with the procedures **1002**, **1014**-**1020** shown FIG. **2**A and illustrated in FIG. **3**B. Thus, FIG. **3**A and FIG. **3**B together illustrate receive flow diplexing for the tunable RF diplexer **10**. As shown in FIG. **3**B, the antenna **12** intercepts the RF receive input signal **16** as electromagnetic waves in free space. These electromagnetic waves result in excitations within the antenna **12**, thereby converting the electromagnetic waves into the RF receive input signal **16**. The first hybrid coupler **18** is configured to receive the RF receive input signal **16** at the first port **86**. The RF receive input signal **16** operates in the same RF communication band as the RF transmission input signal **32** (shown in FIG. **1**). The first hybrid coupler **18** is operable to split the RF receive input signal **16** into the first RF QHRS **112** and the second RF QHRS **114**. Since the first RF QHRS **112** and the second RF QHRS **114** are quadrature hybrids, the first RF QHRS **112** and the second RF QHRS **114** are approximately equal in power but have a quadrature phase difference of 90 degrees or π/2 radians. The first hybrid coupler **18** outputs the first RF QHRS **112** from the third port **90** and outputs the second RF QHRS **114** from the fourth port **92** in response to receiving the RF receive input signal **16** at the first port **86**.

[0078] In the embodiment illustrated in FIG. **3**B, the first RF QHRS **112** is phase-aligned with the RF receive input signal **16**, while the second RF QHRS **114** has a phase difference of about 90 degrees with respect to the RF receive input signal **16**. It should be noted that this may or may not be the case. For example, in alternative embodiments, a phase shift of Δ may be provided between the first port **86** and the third port **90**, and thus, a phase shift of Δ+90 degrees (or π/2 radians) would be provided between the first port **86** and the fourth port **92**.

[0079] The RF filter circuit **22** is operable to reflect the first RF QHRS **112** and the second RF QHRS **114**. As discussed above, the frequency response of the RF filter circuit **22** defines the stopband **66** and the RF filter circuit **22** is tunable so as to shift the stopband **66**. For example, the stopband **66** may be a notch that is shiftable. The tuning circuit **69** is configured to tune the frequency response of the RF filter circuit **22** so that the signal bandwidth of the first RF QHRS **112** and the signal bandwidth of the second RF QHRS **114** are each within the stopband. More specifically, the tuning circuit **69** is configured to shift the stopband **66** of the first RF filter **38**A and the stopband **66** of the second RF filter **38**B into the frequency band of the RF receive input signal **16**. For instance, the tuning circuit **69** may be configured to place the notch within the frequency band of the RF receive input signal **16** so that the notch is centered at the RF receive signal frequency. In this embodiment, the tuning circuit **69** generates the stopband tuning control output **108**. Variable reactive impedance components in both the first RF filter **38**A and the second RF filter **38**B are responsive to the signal level of the stopband tuning control output **108** so as to adjust the variable impedance levels based on the signal level of the stopband tuning control output **108**. As a result, the notch defined by the individual frequency response of the first RF filter **38**A is shifted to include the signal bandwidth of the second RF QHRS **114**. Also, the notch defined by the individual frequency response of the second RF filter **38**B is shifted to include the signal bandwidth of the first RF QHRS **112**. In other words, the notches defined by the individual frequency responses of the first RF filter **38**A and the second RF filter **38**B are placed in the frequency band of the RF receive input signal **16**.

[0080] Since the tuning circuit **69** has tuned the frequency response of the RF filter circuit **22** so that the stopband **66** includes the frequency band of the RF receive input signal **16**, the RF filter circuit **22** blocks the first RF QHRS **112** and the second RF QHRS **114**. Accordingly, the seventh port **98** is substantially isolated from the receive signal flow of the RF receive input signal **16**. The RF filter circuit **22** then reflects the first RF QHRS **112** and the second RF QHRS **114** back to the first hybrid coupler **18**. In the embodiment illustrated in FIG. 3B, the first RF filter **38**A reflects the first RF QHRS **112** back to the first hybrid coupler **18** at the third port **90**. The second RF filter **38**B reflects the second RF QHRS **114** back to the first hybrid coupler **18** at the fourth port **92**.

[0081] The first hybrid coupler **18** is configured to combine the first RF QHRS **112** and the second RF QHRS **114** into the RF receive output signal **28** at the second port **88**. To combine the first RF QHRS **112** and the second RF QHRS **114** into the RF receive output signal **28**, the first hybrid coupler **18** is configured to pass the second RF QHRS **114** from the fourth port **92** to the second port **88**. Additionally, the second hybrid coupler is configured to pass the first RF QHRS **112** from the third port **90** to the second port **88**. However, the first hybrid coupler **18** provides a quadrature phase shift to the first RF QHRS **112** at the second port **88**. Thus, the first RF QHRS **112** is provided substantially as a duplicate of the second RF QHRS **114** at the second port **88**. For example, the phase of the first RF QHRS **112** at the third port **90** is approximately zero degrees. If the phase of the second RF QHRS **114** is 90 degrees at the fourth port **92**, the second RF QHRS **114** has a phase of 90 degrees at the second port **88** since the first hybrid coupler **18** provides no phase shift from the fourth port **92** to the second port **88**. However, due to the quadrature phase shift between the third port **90** and the second port **88**, the first RF QHRS **112** has a phase of about 90 degrees at the second port **88**. Accordingly, the first RF QHRS **112** and the second RF QHRS **114** constructively interfere at the second port **88** to output the RF receive output signal **28** from the second port **88**.

[0082] Also, note that the first hybrid coupler **18** is configured such that the quadrature phase shift at the first port **86** results in destructive interference between the first RF QHRS **112** and the second RF QHRS **114**. Referring again to the previous example, upon reflection of the first RF QHRS **112** and the second RF QHRS **114** by the RF filter circuit **22**, the first RF QHRS **112** appears to have a phase of zero degrees at the first port **86**, but the second RF QHRS **114** appears to have a phase of 180 degrees at the first port **86** due to the quadrature phase shift provided by the first hybrid coupler **18** from the fourth port **92** to the first port **86**. As a result, the first RF QHRS **112** and the second RF QHRS **114** are substantially cancelled at the first port **86**. Consequently, most, if not all, of the power of the first RF QHRS **112** and the second RF QHRS **114** is transferred to the second port **88** and provided in the RF receive output signal **28**. The first hybrid coupler **18** is thus configured to output the RF receive output signal **28** from the second port **88** in response to the first RF QHRS **112** being reflected back by the RF filter circuit **22** to the third port **90** and the second RF QHRS **114** being reflected back by the RF filter circuit **22** to the fourth port **92**. The configuration of the first hybrid coupler **18** and the RF filter circuit **22** thus provides substantial isolation between the second port **88** and the first port **86**.

[0083] It should be noted that due to the differential phase shift provided by the second RF filter **38**B, isolation is provided between the second port **88** for one of the RF communication bands and the seventh port **98** for the other one of the diplexed RF frequency bands. For the following explanation, it is assumed that the first port **86**, the third port **90**, the fourth port **92**, and the second port **88** are port 1, port 2, port 3, and port 4 respectively of the first hybrid coupler **18**. Also, it is assumed that the seventh port **98**, the fifth port **94**, the sixth port **96**, and the eighth port **100** are port 1, port 2, port 3, and port 4 of the second hybrid coupler **20**. Subscripts on the S parameters indicate that the S parameter is either for the first hybrid coupler **18** or the second hybrid coupler **20**. Now, given that the differential phase shift is provided between the fourth port **92** of the first hybrid coupler **18** and the sixth port **96** of the second hybrid coupler **20**, the tunable RF diplexer **10** provides isolation between the second port **88** and the seventh port **98** by assuring that matching of $S(2,4)_{18}*S(1,2)_{20}=S(3,4)_{18}*S(1,3)_{20}$. As a result of the differential phase shift provided by the second RF filter **38**B, the isolation relies on the same sum term of the receive signal flow, which remains approximately true over broad frequency range and thus provides better broadband isolation.

[0084] FIG. 3C illustrates the tunable RF diplexer **10** along with a transmission signal flow of the tunable RF diplexer **10** with respect to the procedures **2000**, **2004-2012** (shown in FIG. 2B) for the RF transmission input signal **30** and the RF transmission output signal **34**. The second hybrid coupler **20** is configured to receive the RF transmission input signal **30** at the seventh port **98**. The eighth port **100** of the second hybrid coupler **20** is isolated from the seventh port **98**. This means that the seventh port **98** is substantially unresponsive to signals incident at the eighth port **100**, and the eighth port **100** is substantially unresponsive to signals incident at the seventh port **98**. As a result, the eighth port **100** is substantially unresponsive to the RF transmission input signal **30** incident at the seventh port **98**.

[0085] The second hybrid coupler **20** is operable to split the RF transmission input signal **30** into a first RF QHTS **116** and a second RF QHTS **118**. In this manner, the first RF QHTS **116** and the second RF QHTS **118** have approximately the same power ratio with respect to the RF transmission input signal **30**, but have a quadrature phase difference of approximately 90 degrees or π/2 radians. The first RF QHTS **116** is output from the fifth port **94**, and the second RF QHTS **118** is output from the sixth port **96**. In the embodiment shown in FIG. **3**C, the seventh port **98** is phase-aligned with the fifth port **94**, while the seventh port **98** has a quadrature phase shift with respect to the sixth port **96**. Thus, the first RF QHTS **116** is approximately phase-aligned with the RF transmission input signal **30**, but there is a quadrature phase difference between the RF transmission input signal **30** and the second RF QHTS **118**.

[0086] Note that in alternative embodiments, this may or may not be the case. For example, there may be a phase shift between the seventh port **98** and the fifth port **94**. The phase shift between the seventh port **98** and the sixth port **96** may then be equal to this phase shift plus the quadrature phase shift of approximately 90 degrees or π/2 radians. Accordingly, so long as the phase difference between the first RF QHTS **116** and the second RF QHTS **118** is about 90 degrees or π/2 radians, phase alignment between the fifth port **94** and the seventh port **98**, and between the sixth port **96** and the seventh port **98**, can vary.

[0087] The first RF QHTS **116** is output at the fifth port **94** to the first RF filter **38**A of the RF filter circuit **22**. Additionally, the second RF QHTS **118** is output at the sixth port **96** to the second RF filter **38**B of the RF filter circuit **22**. The first RF filter **38**A is coupled to the fifth port **94** so as to receive the first RF QHTS **116** from the second hybrid coupler **20**. The second RF filter **38**B is coupled to the sixth port **96** so as to receive the second RF QHTS **118** from the second hybrid coupler **20**. In this embodiment, the second RF filter **38**B is configured to provide a differential phase shift to the second RF QHTS **118**. Accordingly, when the first RF QHTS **116** and the second RF QHTS **118** are output from the RF filter circuit **22**, the phase difference between the first RF QHTS **116** and the second RF QHTS **118** is approximately 270 degrees or 3/2π radians.

[0088] Referring again to FIG. **3**C, the tuning circuit **69** is configured to tune the frequency response of the RF filter circuit **22** so that the passband **62** includes the RF communication band of the RF transmission input signal **30**. The tuning circuit **69** thus shifts the passband **62** of the first RF filter **38**A and the second RF filter **38**B to include the RF communication band of the RF transmission input signal **30**. In this manner, the RF filter circuit **22** is operable to pass the first RF QHTS **116** and the second RF QHTS **118** to the first hybrid coupler **18**. More specifically, by placing the passband **62** in the RF transmission band, the RF filter circuit **22** passes the first RF QHTS **116** and the second RF QHTS **118** to the first hybrid coupler **18**. In this particular embodiment, the first RF filter **38**A passes the first RF QHTS **116** to the first hybrid coupler **18**, while the second RF filter **38**B passes the second RF QHTS **118** to the first hybrid coupler **18**. Spurious emissions of the first RF QHTS **116** and the second RF QHTS **118** are reflected back to the second hybrid coupler **20**. The impedance termination **24** is coupled to the eighth port **100** of the second hybrid coupler **20**. The impedance termination **24** may be a 50 Ohm load. Due to the phase-shifting provided by the second hybrid coupler **20**, the spurious emissions in the RF receive band see a very high (theoretically infinite) impedance level at the seventh port **98**, but only the impedance termination **24** at the eighth port **100**. Thus, the spurious emissions are aggregated to be the aggregated noise signal **110** at the eighth port **100**. This aggregated noise signal **110** is dissipated by the impedance termination **24**.

[0089] Referring again to FIG. **3**C, the first hybrid coupler **18** receives the first RF QHTS **116** from the first RF filter **38**A at the third port **90**. The second RF QHTS **118** is received by the first hybrid coupler **18** from the second RF filter **38**B at the fourth port **92**. As discussed above, the first RF QHTS **116** and the second RF QHTS **118** have a phase difference of about 270 degrees or 3π/2 radians when received by the first hybrid coupler **18**. Thus, for example, if the first RF QHTS **116** has a phase of zero degrees, the second RF QHTS **118** would have a phase of approximately 270 degrees (or 3π/2 radians). From the fourth port **92** to the second port **88**, the first hybrid coupler **18** provides no phase shift. Alternatively, the first hybrid coupler **18** may be configured to provide a phase shift from the third port **90** to the first port **86** of Δ.

[0090] The first hybrid coupler **18** shown in FIG. **3**C is configured to provide a quadrature phase shift from the third port **90** to the second port **88**. In this example, the phase shift is 90 degrees (or π/2 radians), and thus the second RF QHTS **118** has a phase, as seen from the second port **88**, of 270 degrees (note that the second RF QHTS **118** was received with a phase of 270 degrees in this example, and thus is seen with a phase of 270 degrees). Alternatively, the phase shift from the fourth port **92** to the second port **88** may be Δ+90 degrees (or π/2 radians). In any case, the phase difference between the first RF QHTS **116** and the second RF QHTS **118** as seen from the second port **88** is about 180 degrees (note that the first RF QHTS **116** was received with a phase of 0 degrees and thus is seen with a phase of 90 degrees at the second port **88** with quadrature phase shift of 90 degrees between the third port **90** and the second port **88**). Accordingly, the quadrature phase shift at the second port **88** from the third port **90** and the differential phase shift of the second RF filter **38**B results in destructive interference between the first RF QHTS **116** and the second RF QHTS **118** at the second port **88**. As a result, the first RF QHTS **116** and the second RF QHTS **118** are substantially cancelled at the second port **88**. In this manner, the second port **88** is substantially isolated from transmission signal flow for the RF transmission input signal **30** and the RF transmission output signal **34**.

[0091] The first hybrid coupler **18** is configured to output the RF transmission output signal **34** from the first port **86** in response to the first RF QHTS **116** being received from the RF filter circuit **22** at the third port **90** and the second RF QHTS **118** being received from the RF filter circuit **22** at the fourth port **92**. In this particular embodiment, the first hybrid coupler **18** is configured to pass the second RF QHTS **118** from the fourth port **92** to the first port **86**. The first hybrid coupler **18** provides a quadrature phase shift to the second RF QHTS **118** from the fourth port **92** to the first port **86**. The second RF QHTS **118** is thus passed with a phase of 360 degrees to the first port **86** since the second RF QHTS **118** was received at the fourth port **92** with a phase of approximately 270 degrees. Alternatively, the first hybrid coupler **18** may provide a phase shift of Δ to the second RF QHTS **118** when passed from the fourth port **92** to the first port **86**. The first hybrid coupler **18**

is configured to pass the first RF QHTS **116** from the third port **90** to the first port **86**. The first hybrid coupler **18** provides no phase shift to the first RF QHTS **116** at the first port **86**. Thus, the first RF QHTS **116** has a phase of approximately zero at the first port **86**. Alternatively, if a phase shift of Δ+90 degrees (or π/2 radians) 90 degrees (or π/2 radians) were provided to the second RF QHTS **118** from the fourth port **92** to the first port **86**, the quadrature phase shift would be Δ.

[0092] Accordingly, the first RF QHTS **116** is provided substantially as a duplicate of the second RF QHTS **118** at the first port **86**. As a result, the first RF QHTS **116** and the second RF QHTS **118** constructively interfere at the first port **86** to output the RF transmission output signal **34** from the first port **86**. Note that since the first RF QHTS **116** and the second RF QHTS **118** substantially cancel at the second port **88** due to destructive interference, very little or no power is transferred from the first RF QHTS **116** and the second RF QHTS **118** to the second port **88**. Instead most, if not all, of the power in the first RF QHTS **116** and the second RF QHTS **118** is transferred to the first port **86** and provided in the RF transmission output signal **34**.

[0093] FIG. **3**D illustrates the tunable RF diplexer **10** along with the transmission signal flow of the tunable RF diplexer **10** with respect to the procedures **2002**, **2014-2020** shown in FIG. **2**B for the RF transmission input signal **32** and the RF transmission output signal **36**. The procedures **2000**, **2004-2012** and the procedures for the RF transmission input signal **30** and the RF transmission output signal **34** shown in FIG. **2**B and illustrated in FIG. **3**A can performed simultaneously with the procedures **2002**, **2014-2020** shown in FIG. **2**B and illustrated in FIG. **3**D. Thus, FIG. **3**C and FIG. **3**D together illustrates transmission flow diplexing for the tunable RF diplexer **10**. As shown in FIG. **3**B, the first hybrid coupler **18** is operable to receive the RF transmission input signal **32** at the second port **88**. The RF transmission input signal **32** operates within the same RF communication band as the RF receive band of the RF receive input signal **16** (see FIG. **3**B). The first hybrid coupler **18** is operable to split the RF transmission input signal **32** into the first RF QHTS **120** and the second RF QHTS **122**. Since the first RF QHTS **120** and the second RF QHTS **122** are quadrature hybrids, the first RF QHTS **120** and the second RF QHTS **122** are approximately equal in power, but have a quadrature phase difference of 90 degrees or π/2 radians. The first hybrid coupler **18** is operable to output the first RF QHTS **120** from the fourth port **92** and to output the second RF QHTS **122** from the third port **90** in response to receiving the RF transmission input signal **32** at the second port **88**.

[0094] In the embodiment illustrated in FIG. **3**D, the first RF QHTS **120** is phase-aligned with the RF transmission input signal **32**, while the second RF QHTS **122** has a phase difference of about 90 degrees with respect to the RF transmission input signal **32**. It should be noted that this may or may not be the case. For example, in alternative embodiments, a phase shift of Δ (i.e., +45 degrees or π/4 radians) may be provided between the second port **88** and the fourth port **92**, and thus, a phase shift of Δ±90 degrees (or π/2 radians) would be provided between the second port **88** and the third port **90**.

[0095] The RF filter circuit **22** is operable to reflect the first RF QHTS **120** and the second RF QHTS **122**. As discussed above, the frequency response of the RF filter circuit **22** defines the stopband **66**, and the RF filter circuit **22** is tunable so as to shift the stopband. For example, the stopband **66** may be a notch that is shiftable. The tuning circuit **69** is configured to tune the frequency response of the first RF filter **38**A and the second RF filter **38**B of RF filter circuit **22** so that the signal bandwidth of the first RF QHTS **120** and the signal bandwidth of the second RF QHTS **122** are each within the stopband. For instance, the tuning circuit **69** may be configured to place the notch within the RF communication band of the RF transmission input signal **32** so that the notch is centered at the RF transmission signal frequency of the RF transmission input signal **32**. In this embodiment, the tuning circuit **69** generates the stopband tuning control output **108**.

[0096] Since the tuning circuit **69** has tuned the frequency response of the RF filter circuit **22** so that the stopband **66** includes the RF transmission signal band, the RF filter circuit **22** blocks the first RF QHTS **120** and the second RF QHTS **122**. Accordingly, the second hybrid coupler **20** is substantially isolated from the transmission signal flow of the RF transmission input signal **32** and the RF transmission output signal **34**. The second RF filter **38**B then reflects the first RF QHTS **120**, and the first RF filter **38**A reflects the second RF QHTS **122** back to the first hybrid coupler **18**. In the embodiment illustrated in FIG. **3**D, the second RF filter **38**B reflects the first RF QHTS **120** back to the first hybrid coupler **18** at the fourth port **92**. The first RF filter **38**A reflects the second RF QHTS **122** back to the first hybrid coupler **18** at the third port **90**.

[0097] The first hybrid coupler **18** is configured to combine the first RF QHTS **120** and the second RF QHTS **122** into the RF transmission output signal **36** at the first port **86**. To combine the first RF QHTS **120** and the second RF QHTS **122** into the RF transmission output signal **36**, the first hybrid coupler **18** is configured to pass the first RF QHTS **120** from the fourth port **92** to the first port **86**. Additionally, the first hybrid coupler **18** is configured to pass the second RF QHTS **122** from the third port **90** to the first port **86**. However, the first hybrid coupler **18** provides a quadrature phase shift to the first RF QHTS **120** from the fourth port **92** to the first port **86**. Thus, the first RF QHTS **120** is provided substantially as a duplicate of the second RF QHTS **122** at the first port **86**. For example, if the phase of the second RF QHTS **122** is 90 degrees at the third port **90**, the first RF QHTS **120** has a phase of 90 degrees at the first port **86**, since the phase of the first RF QHTS **120** was zero degrees at the fourth port **92**. More specifically, due to the quadrature phase shift between the fourth port **92** and the first port **86**, the first RF QHTS **120** has a phase of about 90 degrees at the first port **86** just like the second RF QHTS **122**. Accordingly, the first RF QHTS **120** and the second RF QHTS **122** constructively interfere at the first port **86** to output the RF transmission output signal **36** from the first port **86**.

[0098] Also, note that the first hybrid coupler **18** is configured such that the quadrature phase shift at the second port **88** results in destructive interference between the first RF QHTS **120** and the second RF QHTS **122**. Referring again to the previous example provided, at the second port **88**, the first RF QHTS **120** appears to have a phase of zero degrees, but the second RF QHTS **122** appears to have a phase of 180 degrees. As a result, the first RF QHTS **120** and the second RF QHTS **122** are substantially cancelled at the second port **88**. Consequently, most, if not all, of the power of the first RF QHTS **120** and the second RF QHTS **122** is transferred to the first port **86** and provided in the RF transmission output signal **36**. The first hybrid coupler **18** is thus configured to output the RF transmission output signal **36** from the first port **86** in response to the first RF QHTS **120** being reflected back by the RF filter circuit **22** to the fourth port **92** and the second RF QHTS **122** being reflected back by the RF filter circuit **22** to the third port **90**.

[0099] It should be noted that due to the differential phase shift provided by the second RF filter **38**B, isolation is provided between the second port **88** for one of the RF communication bands and the seventh port **98** for the other one of the diplexed RF frequency bands. Given that the differential phase shift is provided between the fourth port **92** of the first hybrid coupler **18** and the sixth port **96** of the second hybrid coupler **20**, the tunable RF diplexer **10** provides isolation between the second port **88** and the seventh port **98** by assuring that matching of $S(2,4)_{18}*S(1,2)_{20}=S(3,4)_{18}*S(1,3)_{20}$. As a result of the differential phase shift provided by the second RF filter **38**B, the isolation relies on the same sum term of the transmission signal flow which remains approximately true over broad frequency range and thus provides better broadband isolation for transmission diplexing. In addition to the improved isolation for receive and transmission diplexing, providing the differential phase shift improves the performances of the tunable RF diplexer **10** by tuning the impedance termination **24** to match a load of the antenna **12**.

[0100] FIG. **4** illustrates a circuit diagram of one embodiment of the tunable RF diplexer **10** shown in FIG. **1** and FIGS. **3**A-**3**D. In this embodiment, the first hybrid coupler **18** and the second hybrid coupler **20** are both lumped-element circuits formed as an LCCL network. With regards to the first hybrid coupler **18**, the first port **86**, the second port **88**, the third port **90**, and the fourth port **92** are each provided as nodes. An inductor **124** is connected between the first port **86** and the third port **90** while an inductor **126** is coupled between the second port **88** and the fourth port **92**. The inductor **124** and the inductor **126** are mutually magnetically coupled to one another. A capacitor **128** is connected between the first port **86** and the fourth port **92** while a capacitor **130** is connected between the third port **90** and the second port **88**. In this manner, the appropriate quadrature phase shifts are provided, as described above with respect to FIGS. **3**A-**3**D. With regards to the second hybrid coupler **20**, the fifth port **94**, the sixth port **96**, the seventh port **98**, and the eighth port **100** are also each provided as nodes. An inductor **132** is connected between the fifth port **94** and the seventh port **98**, while an inductor **134** is coupled between the sixth port **96** and the eighth port **100**. The inductor **132** and the inductor **134** are mutually magnetically coupled to one another. A capacitor **136** is connected between the seventh port **98** and the sixth port **96** while a capacitor **138** is connected between the fifth port **94** and the eighth port **100**. In this manner, the appropriate quadrature phase shifts are provided, as described above with respect to FIGS. **3**A-**3**D. An embodiment of the impedance termination **24** is also shown. In this example, the impedance termination **24** is provided as a resistor **140** and a phase shifter **142**. By adjusting a phase of the phase shifter **142**, the impedance load of the impedance termination **24** can be kept at the appropriate characteristic impedance.

[0101] An embodiment of the first RF filter **38**A and the second RF filter **38**B are also shown in FIG. **4**. The first RF filter **38**A includes a parallel resonator **146**A coupled in series with the third port **90**. Additionally, the second RF filter **38**B includes a parallel resonator **146**B coupled in series with the fourth port **92**. As such, the stopband **66** of both the first RF filter **38**A and the second RF filter **38**B are each provided as a notch. The parallel resonator **146**A and the parallel resonator **146**B are thus each an RF notch filter. To provide the passband **62**, both the first RF filter **38**A and the second RF filter **38**B use weakly coupled resonators. With regard to the first RF filter **38**A, the first RF filter **38**A forms a tunable RF filter path **144**A shown in FIG. **4** connected between the third port **90** of the first hybrid coupler **18** and the fifth port **94** of the second hybrid coupler **20**. In order to provide the stopband **66** of the first RF filter **38**A, the first RF filter **38**A includes the parallel resonator **146**A coupled in series with the third port **90** of the first hybrid coupler **18**. The parallel resonator **146**A includes an inductor **148**A and a variable capacitive structure **150**A. As such, the stopband **66** of the first RF filter **38**A is provided as a notch. The variable capacitive structure **150**A has a variable capacitance that is adjusted by the stopband tuning control output **108**. In this manner, the stopband **66** of the first RF filter **38**A can be shifted into the RF communication band of the RF receive input signal **16**, the RF receive output signal **28**, the RF transmission input signal **32**, and the RF transmission output signal **36**.

[0102] With regards to providing the passband **62** of the first RF filter **38**A, the tunable RF filter path **144**A includes an embodiment of a resonator R(1,1) and an embodiment of a resonator R(1,2). The resonator R(1,1) and the resonator R(1,2) are weakly coupled to one another. More specifically, the resonator R(1,1) includes an inductor **152**A and a capacitive structure **154**A. The resonator R(1,2) includes an inductor **156**A and a capacitive structure **158**A.

[0103] The resonator R(1,1) and the resonator R(1,2) are a pair of weakly coupled resonators. The resonator R(1,1) and the resonator R(1,2) are weakly coupled by providing the inductor **152**A and the inductor **156**A such that the inductor **152**A and the inductor **156**A have a weak mutual coupling. Although the resonator R(1,1) and the resonator R(1,2) are weakly coupled, the inductor **156**A has a maximum lateral width and a displacement from the inductor **152**A that is less than or equal to half the maximum lateral width of the inductor **156**A. As such, the inductor **152**A and the inductor **156**A are relatively close to one another. The displacement between the inductor **152**A and the inductor **156**A may be measured from a geometric centroid of the inductor **152**A to a geometric centroid of the inductor **156**A. The maximum lateral width may be a maximum dimension of the inductor **156**A along a plane defined by its largest winding. The weak coupling between the inductor **152**A and the inductor **156**A is obtained through topological techniques. For example, the inductor **152**A and the inductor **156**A may be fully or partially aligned, where winding(s) of the inductor **152**A and winding(s) of the inductor **156**A are configured to provide weak coupling through cancellation. Alternatively or additionally, a plane defining an orientation of the winding(s) of the inductor **152**A and a plane defining an orientation of the winding(s) of the inductor **156**A may be fully or partially orthogonal to one another. Some of the magnetic couplings between the resonators R can be unidirectional (passive or active). This can significantly improve isolation (e.g., isolation in diplexers). In other embodiments, topological techniques are not used to provide weak mutual coupling between the inductor **152**A and the inductor **156**A. Rather, the inductor **152**A and the inductor **156**A are weakly mutually coupled by being sufficiently far apart.

[0104] To maximize the quality (Q) factor of the tunable RF filter paths **144**A through **68**, most of the total mutual coupling should be realized magnetically, and only fine-tuning is provided electrically. While the magnetic coupling can be adjusted only statically, with a new layout design, the electric coupling can be tuned on the fly (after fabrication). The filter characteristics (e.g., bias network structure, resonator capacitance) can be adjusted based on given coupling coefficients to maximize filter performance.

[0105] To provide a tuning range to tune the passband **62** of the tunable RF filter path **144**A and provide a fast roll-off from a low-frequency side to a high-frequency side of the transfer function, the tunable RF filter path **144**A is configured to change a sign of a total mutual coupling coefficient between the resonator R(1,1) and the resonator R(1,2). Accordingly, the tunable RF filter path **144**A includes a cross-coupling capacitive structure C(AP1). As shown in FIG. **4**, the cross-coupling capacitive structure C(AP1) is electrically connected in the tunable RF filter path **144**A between the resonator R(1,1) and the resonator R(1,2) so as to provide a variable coupling coefficient between the resonator R(1,1) and the resonator R(1,2). The cross-coupling capacitive structure C(AP1) is a variable cross-coupling capacitive structure configured to vary the coupling coefficient provided between the resonator R(1,1) and the resonator R(1,2). The passband tuning control output **106** is provided to the cross-coupling capacitive structure C(AP1) to adjust the variable coupling coefficient and thereby shift the passband **62** into the RF communication band of the RF receive input signal **14**, the RF receive output signal **26**, the RF transmission input signal **30**, and the RF transmission output signal **34**.

[0106] In the resonator R(1,1), the inductor **152**A and the capacitive structure **154**A are electrically connected in parallel. More specifically, the inductor **152**A has an end **160**A and an end **162**A, which are disposed opposite to one another. The ends **160**A, **162**A are each electrically connected to the capacitive structure **154**A, which is grounded. Thus, the resonator R(1,1) is a single-ended resonator. The inductor **156**A is also electrically connected in parallel to the capacitive structure **158**A. More specifically, the inductor **156**A has an end **164**A and an end **166**A, which are disposed opposite to one another. The ends **164**A, **166**A are each electrically connected to the capacitive structure **158**A, which is grounded.

[0107] As shown in FIG. **4**, the inductor **152**A and the inductor **156**A are mutually magnetically coupled so as to have a non-inverting mutual coupling and the no phase inversion is provided by the first RF filter **38**A. In this embodiment, the resonator R(1,1) and the resonator R(1,2) are single-ended resonators. The inductor **152**A is magnetically coupled to the inductor **156**A such that an RF signal received at the end **160**A of the inductor **152**A with a voltage polarity (i.e., either a positive voltage polarity or a negative voltage polarity) results in a filtered RF signal being transmitted out the end **164**A of the inductor **156**A with the same voltage polarity. Also, the inductor **156**A is magnetically coupled to the inductor **152**A such that an RF signal received at the end **164**A of the inductor **156**A with a voltage polarity (i.e., either a positive voltage polarity or a negative voltage polarity) results in a filtered RF signal being transmitted out the end **160**A of the inductor **152**A with the same voltage polarity. This is indicated in FIG. **4** by the dot convention where a dot is placed at the end **160**A of the inductor **152**A, and a dot is placed at the end **164**A of the inductor **156**A. Additionally, the inductors **152**A, **156**A may be magnetically coupled so as to have a low magnetic coupling coefficient through field cancellation, with the variable coupling coefficient. In this case, the inductor **152**A and the inductor **156**A are arranged such that the inductor **156**A reduces a mutual magnetic coupling coefficient of the inductor **152**A.

[0108] The resonator R(1,2) is operably associated with the resonator R(1,1) such that an energy transfer factor between the resonator R(1,1) and the resonator R(1,2) is less than 10%. Thus, the resonator R(1,1) and the resonator R(1,2) are weakly coupled. A total mutual coupling between the resonator R(1,1) and the resonator R(1,2) is provided by a sum total of the mutual magnetic factor between the resonator R(1,1) and the resonator R(1,2) and the mutual electric coupling coefficient is between the resonator R(1,1) and the resonator R(1,2). In this embodiment, the mutual magnetic coupling coefficient between the inductor **152**A and the inductor **156**A is a fixed mutual magnetic coupling coefficient. Although embodiments of the resonators R(1,1), R(1,2) may be provided so as to provide a variable magnetic coupling coefficient between the resonators R(1,1), R(1,2), embodiments of the resonators R(1,1), R(1,2) that provide variable magnetic couplings can be costly and difficult to realize. However, providing variable electric coupling coefficients is easier and more economical. Thus, using the cross-coupling capacitive structure C(AP1) to provide the variable electric coupling coefficient is an economical technique for providing a tunable filter characteristic between the resonators R(1,1), R(1,2). Furthermore, since the mutual magnetic coupling coefficient between the inductor **152**A and the inductor **156**A is fixed, the tunable RF filter path **144**A has lower insertion losses. A matching capacitor **168**A is connected in series with the fifth port **94** of the first hybrid coupler **18**.

[0109] With regard to the second RF filter **38**B, the second RF filter **38**B forms a tunable RF filter path **144**B shown in FIG. **4** connected between the fourth port **92** of the first hybrid coupler **18** and the sixth port **96** of the second hybrid coupler **20**. In order to provide the stopband **66** of the second RF filter **38**B, the second RF filter **38**B includes a parallel resonator **146**B coupled in series with the third port **90** of the first hybrid coupler **18**. The parallel resonator **146**B includes an inductor **148**B and a variable capacitive structure **150**B. As such the stopband **66** is provided as a notch. The variable capacitive structure **150**B has a variable capacitance that is adjusted by the stopband tuning control output **108**. In this manner, the stopband **66** can be shifted into the RF communication band of the RF receive input signal **16**, the RF receive output signal **28**, the RF transmission input signal **32**, and the RF transmission output signal **36**.

[0110] With regards to providing the passband **62** of the second RF filter **38**B, the tunable RF filter path **144**B includes an embodiment of a resonator R(2,1) and an embodiment of a resonator R(2,2). The resonator R(2,1) and the resonator R(2,2) are weakly coupled to one another. More specifically, the resonator R(2,1) includes an inductor **152**B and a capacitive structure **154**B. The resonator R(2,2) includes an inductor **156**B and a capacitive structure **158**B.

[0111] The resonator R(2,1) and the resonator R(2,2) are a pair of weakly coupled resonators. The resonator R(2,1) and the resonator R(2,2) are weakly coupled by providing the inductor **152**B and the inductor **156**B such that the inductor **152**B and the inductor **156**B have a weak mutual coupling. Although the resonator R(2,1) and the resonator R(2,2) are weakly coupled, the inductor **156**B has a maximum lateral width and a displacement from the inductor **152**B that is less than or equal to half the maximum lateral width of the inductor **156**B. As such, the inductor **152**B and the inductor **156**B are relatively close to one another. The displacement between the inductor **152**B and the inductor **156**B may be measured from a geometric centroid of the inductor **152**B to a geometric centroid of the inductor **156**B. The maximum lateral width may be a maximum dimension of the inductor **156**B along a plane defined by its largest winding. The weak coupling between the inductor **152**B and the inductor **156**B is obtained through topological techniques. For example, the inductor **152**B and the inductor **156**B may be fully or partially aligned, where winding(s) of the inductor **152**B and winding(s) of the inductor **156**B are configured to provide weak coupling through cancellation. Alternatively or additionally, a plane defining an orientation of the winding(s) of the inductor **152**B and a plane defining an orientation of the winding(s) of the inductor **156**B may be fully or partially orthogonal to one another. Some of the magnetic couplings between the resonators R can be unidirectional (passive or active). This can significantly improve isolation (e.g., isolation in diplexers). In other embodiments, topological techniques are not used to provide weak mutual coupling between the inductor **152**B and the inductor **156**B. Rather, the inductor **152**B and the inductor **156**B are weakly mutually coupled by being sufficiently far apart.

[0112] To maximize the quality (Q) factor of the tunable RF filter paths **144**B through **68**, most of the total mutual coupling should be realized magnetically, and only fine-tuning is provided electrically. This also heLFS to reduce common-mode signal transfer in the differential resonators and thus keeps the Q factor high. While the magnetic coupling can be adjusted only statically, with a new layout design, the electric coupling can be tuned on the fly (after fabrication). The filter characteristics (e.g., bias network structure, resonator capacitance) can be adjusted based on given coupling coefficients to maximize filter performance.

[0113] To provide a tuning range to tune the passband **62** of the tunable RF filter path **144**B and provide a fast roll-off from a low-frequency side to a high-frequency side of the transfer function, the tunable RF filter path **144**B is configured to change a sign of a total mutual coupling coefficient between the resonator R(2,1) and the resonator R(2,2). Accordingly, the tunable RF filter path **144**B includes a cross-coupling capacitive structure C(BP1). As shown in FIG. **4**, the cross-coupling capacitive structure C(BP1) is electrically connected in the tunable RF filter path **144**B between the resonator R(2,1) and the resonator R(2,2) so as to provide a variable coupling coefficient between the resonator R(2,1) and the resonator R(2,2). The cross-coupling capacitive structure C(BP1) is a variable cross-coupling capacitive structure configured to vary the coupling coefficient provided between the resonator R(2,1) and the resonator R(2,2). The passband tuning control output **106** is provided to the cross-coupling capacitive structure C(BP1) to adjust the variable coupling coefficient and thereby shift the passband **62** into the RF communication band of the RF receive input signal **14**, the RF receive output signal **26**, the RF transmission input signal **30**, and the RF transmission output signal **34**.

[0114] In the resonator R(2,1), the inductor **152**B and the capacitive structure **154**B are electrically connected in parallel. More specifically, the inductor **152**B has an end **160**B and an end **162**B, which are disposed opposite to one another. The ends **160**B, **162**B are each electrically connected to the capacitive structure **154**B, which is grounded. Thus, the resonator R(2,1) is a single-ended resonator. The inductor **156**B is also electrically connected in parallel to the capacitive structure **158**B. The inductor **156**B has an end **164**B and an end **166**B, which are disposed opposite to one another. The ends **164**B, **166**B are each electrically connected to the capacitive structure **158**B, which is grounded.

[0115] As shown in FIG. **4**, the inductor **152**B and the inductor **156**B are mutually magnetically coupled so as to have a inverting mutual coupling and provide the differential phase inversion with the second RF filter **38**B. The inductor **152**B is magnetically coupled to the inductor **156**B such that an RF signal received at the end **160**B of the inductor **152**B with a voltage polarity (i.e., either a positive voltage polarity or a negative voltage polarity) results in a filtered RF signal being transmitted out the end **166**B of the inductor **156**B with the same voltage polarity. Also, the inductor **156**B is magnetically coupled to the inductor **152**B such that an RF signal received at the end **164**B of the inductor **156**B with a voltage polarity (i.e., either a positive voltage polarity or a negative voltage polarity) results in a filtered RF signal being transmitted out the end **162**B of the inductor **152**B with the same voltage polarity. This is indicated in FIG. **4** by the dot convention where a dot is placed at the end **160**B of the inductor **152**B and a dot is placed at the end **164**B of the inductor **156**B. Additionally, the inductors **152**B, **156**B may be magnetically coupled so as to have a low magnetic coupling coefficient through field cancellation, with the variable coupling coefficient. In this case, the inductor **152**B and the inductor **156**B are arranged such that the inductor **156**B reduces a mutual magnetic coupling coefficient of the inductor **152**B.

[0116] The resonator R(2,2) is operably associated with the resonator R(2,1) such that an energy transfer factor between the resonator R(2,1) and the resonator R(2,2) is less than 10%. Thus, the resonator R(2,1) and the resonator R(2,2) are weakly coupled. A total mutual coupling between the resonator R(2,1) and the resonator R(2,2) is provided by a sum total of the mutual magnetic factor between the resonator R(2,1) and the resonator R(2,2) and the mutual electric coupling coefficients between the resonator R(2,1) and the resonator R(2,2). In this embodiment, the mutual magnetic coupling coefficient between the inductor **152**B and the inductor **156**B is a fixed mutual magnetic coupling coefficient. Although embodiments of the resonators R(2,1), R(2,2) may be provided so as to provide a variable magnetic coupling coefficient between the resonators R(2,1), R(2,2), embodiments of the resonators R(2,1), R(2,2) that provide variable magnetic couplings can be costly and difficult to realize. However, providing variable electric coupling coefficients is easier and more economical. Thus, using the cross-coupling capacitive structure C(BP1) to provide the variable electric coupling coefficients is an economical technique for providing a tunable filter characteristic between the resonators R(2, 1), R(2,2). Furthermore, since the mutual magnetic coupling coefficient between the inductor **152**B and the inductor **156**B is fixed, the tunable RF filter path **144**B has lower insertion losses. A matching capacitor **168**B is connected in series with the sixth port **96** of the second hybrid coupler **20**. In this embodiment, the resonator R(2,1) and the resonator R(2,2) are single-ended resonators.

[0117] FIG. **5** illustrates S parameters for the tunable RF diplexer **10** shown in FIG. **4** where the tunable RF diplexer **10** has been tuned to center the passband **62** of the first RF filter **38**A and the second RF filter **38**B in the ISM frequency band centered around 2.44 GHz. The stopband **66** of the first RF filter **38**A and the second RF filter **38**B is centered in MB/HB frequency bands from 1.7 GHz to 2.9 GHz. An S(86, 88) parameter is an S parameter of the tunable RF diplexer **10** between the first port **86** and the second port **88**. The S(86,88) parameter shows that the transfer response of the tunable RF diplexer **10** remains at around 0 dB except around the ISM frequency band. Accordingly, the tunable RF diplexer **10** is configured to have small insertion losses in the MB/HB frequency bands between the first port **86** and the second port **88**. An S(86, 98) parameter is an S parameter of the tunable RF diplexer **10** between the first port **86** and the seventh port **98**. The S(86,98) parameter shows that the transfer response of the tunable RF diplexer **10** increases to around 0 dB in the ISM frequency band and decreases relatively quickly outside the ISM frequency band. Accordingly, the tunable RF diplexer **10** is configured to have small insertion losses in the ISM frequency bands between the first port **86** and the seventh port **98**. An S(88, 98) parameter is an S parameter of the tunable RF diplexer **10** between the second port **88** and the seventh port **98**. The S(88, 98) parameter is not explicitly shown because it remains below 50 dB and is −51.077 dB at the center frequency of the ISM band. The S(88,98) parameter shows that the transfer response of the tunable RF diplexer **10** provides improved isolation between the second port **88** for the MB/HB frequency bands and the seventh port **98** for the ISM frequency band due to the differential phase shift provided by the second RF filter **38**B. Accordingly, the performance of the tunable RF diplexer **10** is enhanced by the differential phase shift.

[0118] FIG. **6** illustrates another embodiment of the tunable RF diplexer **10** shown in FIG. **1**. The tunable RF diplexer **10** shown in FIG. **1** is similar to the embodiment shown in FIG. **4**. However, in this embodiment, the inductor **152**A of the resonator R(1,1) and the inductor **156**A of the resonator R(1,2) form a first single-ended transformer. The resonator R(1,1) and the resonator R(1,2) are weakly coupled and are single-ended resonators, as explained above with respect to FIG. **4**. Similarly, the inductor **152**B of the resonator R(2,1) and the inductor **156**B of the resonator R(2,2) also form a second single-ended transformer. The resonator R(2,1) and the resonator R(2,2) are weakly coupled, as explained above with respect to FIG. **4**. The second single-ended transformer provided by the inductor **152**B and the inductor **156**B provides the differential phase shift between the fourth port **92** of the first hybrid coupler **18** and the sixth port **96** of the second hybrid coupler **20**, as described above with respect to FIGS. **3**A-**3**D. Since the first single-ended transformer and the second single ended transformer are provided in the first RF filter **38**A and the second RF filter **38**B, the capacitive structure C(PA1) (shown in FIG. **4**) and the capacitive structure C(PB1) (shown in FIG. **4**) are not provided.

[0119] FIG. **7** illustrates S parameters for the tunable RF diplexer **10** shown in FIG. **6** where the tunable RF diplexer **10** has been provided to center the passband **62** of the first RF filter **38**A, and the second RF filter **38**B in the ISM frequency band is centered around 2.44 GHz. The stopband **66** of the first RF filter **38**A and the second RF filter **38**B is centered in MB/HB frequency bands from 1.7 GHz to 2.9 GHz. The S(86,88) parameter shows that the transfer response of the tunable RF diplexer **10** remains at around 0 dB except around the ISM frequency band. Accordingly, the tunable RF diplexer **10** is configured to have small insertion losses in the MB/HB frequency bands between the first port **86** and the second port **88**. The S(86,98) parameter shows that the transfer response of the tunable RF diplexer **10** increases to around 0 dB in the ISM frequency band and decreases relatively quickly outside the ISM frequency band. Accordingly, the tunable RF diplexer **10** is configured to have small insertion losses in the ISM frequency bands between the first port **86** and the seventh port **98**. The S(88, 98) remains below 40 dB and shows that the transfer response of the tunable RF diplexer **10** provides improved isolation between the second port **88** for the MB/HB frequency bands and the seventh port **98** for the ISM frequency band due to the differential phase shift provided by the second RF filter **38**B. Accordingly, the performance of the tunable RF diplexer **10** is enhanced by the differential phase shift.

[0120] FIG. **8** illustrates another embodiment of the tunable RF diplexer **10** shown in FIG. **1** and is similar to the embodiment illustrated in FIG. **4**. With respect to the first RF filter **38**A, the resonator R(1,1) and the resonator R(1,2) are weakly coupled resonators, as explained above. However, in this embodiment, the resonator R(1,1) is a differential resonator, and the resonator R(1,2) is a differential resonator. With regard to the resonator R(1,1) shown in FIG. **8**, the inductor **152**A has a grounded center tap so that the inductor **152**A has an inductor portion **170**A between the end **160**A and the center tap, and an inductor portion **172**A between the center tap and the end **162**A. In this embodiment, the capacitive structure **154**A is connected between the end **160**A of the inductor **152**A and ground. A capacitive structure **154**A' is connected between the end **162**A of the inductor **152**A and ground. The resonator R(1,1) thus forms a differential resonator.

[0121] With regard to the resonator R(1,2) shown in FIG. **8**, the inductor **156**A has a grounded center tap so that the inductor **156**A has an inductor portion **174**A between the end **164**A and the center tap, and an inductor portion **176**A between the center tap and the end **166**A. In this embodiment, the capacitive structure **158**A is connected between the end **164**A of the inductor **156**A and ground. A capacitive structure **158**A' is connected between the end **166**A of the inductor **156**A and ground. The resonator R(1,2) thus also forms a differential resonator.

[0122] The inductor **152**A of the resonator R(1,1) and the inductor **156**A of the resonator (1,2) form a differential transformer. The differential transformer provides no phase shift. More specifically, the inductor portion **170**A of the inductor **152**A is magnetically coupled to the inductor portion **174**A of the inductor **156**A. The inductor portion **172**A of the inductor **152**A is magnetically coupled to the inductor portion **176**A of the inductor **156**A. As such, a differential RF signal having a positive side signal received at the end **160**A of the inductor **152**A and a negative side being transmitted out of the end **162**A of the inductor **152**A results in a filtered differential RF signal having a positive side transmitted out the end **164**A of the inductor **156**A and a negative side transmitted into the end **166**A of the inductor **156**A. In this embodiment, the first RF filter **38**A includes an inductor **178**A that is coupled to the third port **90** of the first hybrid coupler **18**. The inductor **178**A is magnetically coupled to the inductor **154**A of the resonator R(1,1) so that the inductor **178**A and the inductor **154**A form a single-ended to differential transformer. Similarly, the first RF filter **38**A includes an inductor **180**A coupled to the fifth port **94**. The inductor **180**A is magnetically coupled to the inductor **156**A of the resonator R(1,2) so that the inductor **180**A and the inductor **156**A form another single-ended to differential transformer.

[0123] With respect to the second RF filter **38**B, the resonator R(2,1) and the resonator R(2,2) are weakly coupled resonators, as explained above. However, in this embodiment, the resonator R(2,1) is a differential resonator, and the resonator R(2,2) is a differential resonator. With regard to the resonator R(2,1) shown in FIG. **8**, the inductor **152**B has a grounded center tap so that the inductor **152**B has an inductor portion **170**B between the end **160**B and the center tap, and an inductor portion **172**B between the center tap and the end **162**B. In this embodiment, the capacitive structure **154**B is connected between the end **160**B of the inductor **152**B and ground. A capacitive structure **154**B' is connected between the end **162**B of the inductor **152**B and ground. The resonator R(2,1) thus forms a differential resonator.

[0124] With regard to the resonator R(2,2) shown in FIG. **8**, the inductor **156**B has a grounded center tap so that the inductor **156**B has an inductor portion **174**B between the end **164**B and the center tap, and an inductor portion **176**B between the center tap and the end **166**B. In this embodiment, the capacitive structure **158**B is connected between the end **164**B of the inductor **156**B and ground. A capacitive structure **158**B' is connected between the end **166**B of the inductor **156**B and ground. The resonator R(2,2) thus also forms a differential resonator.

[0125] The inductor **152**B of the resonator R(2,1) and the inductor **156**B of the resonator (2,2) form a differential transformer. The differential transformer provides the differential phase shift discussed above with respect to FIGS. **3**A-**3**D. More specifically, the inductor portion **170**B of the inductor **152**B is magnetically coupled to the inductor portion **176**B of the inductor **156**B. The inductor portion **172**B of the inductor **152**B is magnetically coupled to the inductor portion **174**B of the inductor **156**B. As such, a differential RF signal having a positive side signal received at the end **160**B of the inductor **152**B and a negative side being transmitted out of the end **162**B of the inductor **152**B results in a filtered differential RF signal having a positive side transmitted into the end **166**B of the inductor **156**B and a negative side transmitted out of the end **164**B of the inductor **156**B. Providing the differential phase shift with the differential transformer formed by the inductor **152**B and the inductor **156**B improves the performance of the tunable RF diplexer **10** shown in FIG. **9** since the differential transformer has less dependency on common mode inductances.

[0126] In this embodiment, the second RF filter **38**B includes an inductor **178**B that is coupled to the fourth port **92** of the first hybrid coupler **18**. The inductor **178**B is magnetically coupled to the inductor **152**B of the resonator R(2,1) so that the inductor **178**B and the inductor **152**B form a single-ended to differential transformer. Similarly, the second RF filter **38**B includes an inductor **180**B coupled to the sixth port **96** of the second hybrid coupler **20**. The inductor **180**B is magnetically coupled to the inductor **156**B of the resonator R(2,2) so that the inductor **180**B and the inductor **156**B form another single-ended to differential transformer.

[0127] FIG. **9** illustrates another embodiment of the tunable RF diplexer **10** shown in FIG. **1**, which is the same as the embodiment shown in FIG. **8** except in the manner that the second RF filter **38**B provides the differential phase shift. Unlike the embodiment shown in FIG. **8**, the differential transformer formed through the weak magnetic coupling of the inductor **152**B of the resonator R(2,1), and the inductor **156**B of the resonator R(2,2) shown in FIG. **9** provides approximately no phase shift. In this embodiment, the differential transformer is provided by the inductor **152**B of the resonator R(2,1) and the inductor **156**B of the resonator R(2, 2). Accordingly, in this embodiment, the inductor portion **170**B of the inductor **152**B is magnetically coupled to the inductor portion **174**B of the inductor **156**B. The inductor portion **172**B of the inductor **152**B is magnetically coupled to the inductor portion **176**B of the inductor **156**B. As such, a differential RF signal having a positive side signal received at the end **160**B of the inductor **152**B and a negative side being transmitted out of the end **162**B of the inductor **152**B results in a filtered differential RF signal having a positive side transmitted out the end **164**B of the inductor **156**B and a negative side transmitted into the end **166**B of the inductor **156**B.

[0128] Instead, the differential phase shift is provided by the single to differential transformer formed by the inductor **156**B of the resonator R(2,2) and the inductor **180**B. More specifically, the inductor **156**B and the inductor **180**B are magnetically coupled such that the single to differential transformer provides the differential phase shift, as shown in FIG. **9**. In alternative embodiments, the single to differential transformer formed by the inductor **178**B and the inductor **152**B of the resonator R(1,1) provide the differential shift. More specifically, in these alternative embodiments, the inductor **178**B and the inductor **152**B of the resonator R(1,1) are magnetically coupled such that the single to differential transformer provides the differential phase shift.

[0129] FIG. **10** illustrates another embodiment of a tunable RF diplexer **10**A. The tunable RF diplexer **10**A provides diplexing to the RF input receive signal **14**, the RF receive input signal **16**, the RF receive output signal **26**, the RF receive output signal **28**, the RF transmission input signal **30**, the RF transmission input signal **32**, the RF transmission output signal **34**, and the RF transmission output signal **36** in the same manner described above with respect to FIGS. **1**, **2**A-**2**B, and **3**A-**3**D, except that in this embodiment the second RF filter **38**B does not provide the differential phase shift. Instead, the phase inversion component is provided by a phase shifter **182**. Thus, while the second RF filter **38**B in FIG. **10** provides no phase shift, the phase shifter **182** shown in FIG. **10** provides a differential phase shift. The phase shifter **182** is thus the phase inversion component. In this embodiment, the phase shifter **182** is configured to provide a positive differential phase shift of approximately +180 degrees or π radians.

[0130] As shown in FIG. **10**, the phase shifter **182** is connected between the fourth port **92** of the first hybrid coupler **18** and the second RF filter **38**B of the RF filter circuit **22**. Using the phase shifter **182** to provide the differential phase shift (e.g., the positive differential phase shift) is advantageous since the phase shifter **182** can be included to provide the differential phase shift over a wide frequency range. Thus, the tunable RF diplexer **10**A in FIG. **10** is operable to provide broadband isolation from the seventh port **98** to the second port **88**.

[0131] FIG. **11** illustrates another embodiment of the tunable RF diplexer **10**A. The tunable RF diplexer **10**A shown in FIG. **11** is the same as the embodiment shown in FIG. **11**, except in this embodiment, the phase shifter provides a negative differential phase shift of approximately 180 degrees or 1π radians. The phase shifter **182** is thus the differential phase shifting component. The tunable RF diplexer **10**A in FIG. **11** is also operable to provide broadband isolation from the seventh port **98** to the second port **88**.

[0132] FIG. **12** illustrates another embodiment of a tunable RF diplexer **10**B. The tunable RF diplexer **10**B provides diplexing to the RF input receive signal **14**, the RF receive input signal **16**, the RF receive output signal **26**, the RF receive output signal **28**, the RF transmission input signal **30**, the RF transmission input signal **32**, the RF transmission output signal **34**, and the RF transmission output signal **34** in the same manner described above with respect to FIGS. **1**, **2**A-**2**B, and **3**A-**3**D, except that in this embodiment the second RF filter **38**B also does not provide the differential phase shift. Instead, the phase inversion component is provided as a single to differential transformer connected to the second RF filter **38**B, as explained in further detail below.

[0133] In this embodiment, a single to differential transformer **184**A is connected between the third port **90** and the first RF filter **38**A. The single to differential transformer **184**A includes an inductor **186**A connected to the third port **90**. An inductor **188**A is magnetically coupled to the inductor **186**A has a grounded center tapped. The single to differential transformer **184**A shown in FIG. **12** does not provide a differential phase shift. In this embodiment, the inductor **186**A is connected to the first RF filter **38**A. Another single to differential transformer **190**A is connected between the first RF filter **38**A and the fifth port **94** of the second hybrid coupler **20**. The single to differential transformer **190**A includes an inductor **192**A connected to the first RF filter **38**A. An inductor **194**A is magnetically coupled to the inductor **192**A and has a grounded center tap. The inductor **194**A is connected to the fifth port **94** of the second hybrid coupler **20**. The single to differential transformer **190**A shown in FIG. **12** does not provide a phase shift.

[0134] Also in this embodiment, a single to differential transformer **184**B is connected between the fourth port **92** of the first hybrid coupler **18** and the second RF filter **38**B. The single to differential transformer **184**B includes an inductor **186**B connected to the fourth port **92**. An inductor **188**B is magnetically coupled to the inductor **186**B has a grounded center tapped. The single to differential transformer **184**B shown in FIG. **12** provides a differential phase shift and is thus the phase inversion component. In this embodiment, the inductor **186**B is connected to the second RF filter **38**B such that there is an inversion of the differential polarity provided to the second RF filter **38**B. As such, the single to differential transformer **184**B provides the differential phase shift and is the phase inversion component. Another single to differential transformer **190**B is connected between the second RF filter **38**B and the sixth port **96**. The single to differential transformer **190**B includes an inductor **192**B connected to the second RF filter **38**B. An inductor **194**B is magnetically coupled to the inductor **192**B and has a grounded center tap. The inductor **194**B is connected to the sixth port **96** of the second hybrid coupler **20**. The single to differential transformer **190**B shown in FIG. **12** does not provide a phase shift. In alternative embodiment, the single to differential transformer **190**B is provided as the phase inversion component to provide the differential phase shift. For example, the inductor **192**B may be connected to the second RF filter **38**B such that there is an inversion of the differential polarity provided from the second RF filter **38**B.

[0135] FIG. **13** illustrates a circuit diagram of another embodiment of the tunable RF diplexer **10** shown in FIG. **1** and FIGS. **3**A-**3**D, wherein the tunable RF diplexer **10** shown in FIG. **13** is the same as the embodiment shown in FIG. **4**, except in this embodiment, the tunable RF diplexer **10** further includes a cross-coupling capacitive structure C(AP2), a cross-coupling capacitive structure C(BP2), a cross-coupling capacitive structure CC(A1), a cross-coupling capacitive structure CC(A2), a cross-coupling capacitive structure CC(B1), and a cross-coupling capacitive structure CC(B2). As explained in further detail below, by providing the cross-coupling capacitive structure CC(A2), the cross-coupling capacitive structure CC(B1), and the cross-coupling capacitive structure CC(B2), the RF filter circuit **22** is tunable to provide the stopband **66**, which in this embodiment is a notch, on both a high-frequency side of the passband **62** and a low-frequency side of the passband **62**. This can resolve problems that may result when the RF communication band **44** for operation at the second port **88** gets too close to the RF communication band **48** of operation at the seventh port **98**.

[0136] For example, when the RF communication band **44** is a B7 transmission frequency band centered around 2.504 GHz and the RF communication band **48** is the ISM frequency band centered around 2.44 GHz, it becomes more difficult for the tunable RF circuit **22** to pass and reflect appropriately as described in FIGS. **3**A-**3**D. This can result in the tunable RF circuit **22** experiencing high insertion losses. Additionally, this can also result in degradation of isolation in the tunable RF diplexer **10**. To help correct this and provide better performance, the tuning circuit **69** is configured to tune the RF filter circuit **22** to switch the stopband **66** (e.g., in this case, the notch) (shown in FIG. **2**D) from the high-frequency side of the passband **62** (shown in FIG. **2**D) to the low-frequency side of the passband **62** as a result of the RF communication band **48** (shown in FIG. **2**D) for operation at the second port **88** being changed from HB frequency bands to MB frequency bands that are close to the ISM frequency band, such as the B7 transmission frequency band. This allows for the tunable RF diplexer **10** shown in FIG. **13** to have less insertion loss and better isolation when the RF communication band **48** is in the B7 transmission frequency band. The tuning circuit **69** is configured also to tune the RF filter circuit **22** to switch the stopband **66** (e.g., in this case, the notch) from the low-frequency side of the passband **62** to the high-frequency side of the passband **62** as a result of the RF communication band **48** for operation at the second port **88** being changed from MB frequency bands that are close to the ISM frequency band to HB frequency bands. The tuning circuit **69** is operable to switch the stopband **66** (e.g., in this case, the notch) from to and from the low-frequency side and the high-frequency side of the passband **62** by adjusting variable capacitances in the cross-coupling capacitive structure CC(A2), the cross-coupling capacitive structure CC(B1), and the cross-coupling capacitive structure CC(B2), as explained in further detail below.

[0137] With respect to the RF filter **38**A shown in FIG. **13**, the tunable RF filter path **144**A further includes the cross-coupling capacitive structure C(AP2). As shown in FIG. **13**, the cross-coupling capacitive structure C(AP2) is electrically connected in the tunable RF filter path **144**A between the resonator R(1,1) and the resonator R(1,2) so as to provide a variable coupling coefficient between the resonator R(1,1) and the resonator R(1,2). The cross-coupling capacitive structure C(AP2) is a variable cross-coupling capacitive structure configured to vary the coupling coefficient provided between the resonator R(1,1) and the resonator R(1,2). The passband tuning control output **106** is provided to the cross-coupling capacitive structure C(AP2) to adjust the variable coupling coefficient and thereby shift the passband **62** into the RF communication band of the RF receive input signal **14**, the RF receive output signal **26**, the RF transmission input signal **30**, and the RF transmission output signal **34**. As described above, the resonator R(1,1) and the resonator R(1,2) are connected to provide the passband **62** of the tunable RF filter path **144**A, and thus a bandpass filter is formed with the resonator R(1,1) and the resonator R(1,2). The stopband **66** of the RF filter **38**A in this case is a notch provided by the parallel resonator **146**A connected in series at the third port **90**. Accordingly, the parallel resonator **146**A is a notch filter.

[0138] The RF filter **38**A is tunable to provide the stopband **66** (e.g., in this case, the notch) of the RF filter **38**A on both a high-frequency side of the passband **62** and a low-frequency side of the passband **62**. As in FIG. **4**, the RF filter **38**A in FIG. **13** is provided by the tunable RF filter path **144**A. In order for the RF filter **38**A to be tunable to provide the stopband **66** (e.g., in this case, the notch) of the RF filter **38**A on both the high-frequency side of the passband **62** and the low-frequency side of the passband **62**, the RF filter **38**A includes the cross-coupling capacitive structure CC(A1) and the cross-coupling capacitive structure CC(A2). The cross-coupling capacitive structure CC(A1) has a variable capacitance, and the cross-coupling capacitive structure CC(A2) also has a variable capacitance. The stopband tuning control output **108** is provided to the cross-coupling capacitive structure CC(A1) and the cross-coupling capacitive structure CC(A2) to adjust their variable capacitances and so that the stopband **66** (e.g., in this case, the notch) is transposed to and from the low-frequency side and the high frequency side of the passband **62** provided by the RF filter **38**A. In essence, the cross-coupling capacitive structure CC(A1) and the cross-coupling capacitive structure CC(A2) are connected to introduce factors into an equation describing the relationship between the resonators R(1,1), R(1,2) and the variable coupling coefficients provided by the capacitive structures C(AP1), C(AP2) that allow for the stopband **66** (e.g., in this case, the notch) to be switched to and from the high-frequency side and the low-frequency side of the passband **62** of the tunable RF filter path **144**A.

[0139] Accordingly, the cross-coupling capacitive structure CC(A1) and the cross-coupling capacitive structure CC(A2) are coupled such that the tunable RF filter path **144**A is tunable to provide the stopband **66** (e.g., in this case, the notch) of the RF filter **38**A on both the high-frequency side of the first passband and the low-frequency side of the first passband by varying the first variable capacitance and the second variable capacitance. In this embodiment, the cross-coupling capacitive structure CC(A1) is electrically connected from the third port **90** to the resonator R(2,2). The resonator R(2,2) in the tunable RF filter path **144**A is connected closest to the fifth port **94** of the second hybrid coupler **20**. Furthermore, the cross-coupling capacitive structure CC(A2) is electrically connected from the fifth port **94** to the resonator R(1,1). The resonator R(1,1) in the tunable RF filter path **144**A is connected closest to the third port **90** of the first hybrid coupler **18**.

[0140] With respect to the RF filter **38**B shown in FIG. **13**, the tunable RF filter path **144**B further includes a cross-coupling capacitive structure C(BP2). As shown in FIG. **13**, the cross-coupling capacitive structure C(BP2) is electrically connected in the tunable RF filter path **144**B between the resonator R(2,1) and the resonator R(2,2) so as to provide a variable coupling coefficient between the resonator R(2,1) and the resonator R(2,2). The cross-coupling capacitive structure C(BP2) is a variable cross-coupling capacitive structure configured to vary the coupling coefficient provided between the resonator R(2,1) and the resonator R(2,2). The passband tuning control output **106** is provided to the cross-coupling capacitive structure C(BP2) to adjust the variable coupling coefficient and thereby shift the passband **62** into the RF communication band of the RF receive input signal **14**, the RF receive output signal **26**, the RF transmission input signal **30**, and the RF transmission output signal **34**. As described above, the resonator R(2,1) and the resonator R(2,2) are connected to provide the passband **62** of the tunable RF filter path **144**B, and thus a bandpass filter is formed with the resonator R(2,1) and the resonator R(2,2). The stopband **66** of the RF filter **38**B in this case is a notch provided by the parallel resonator **146**B connected in series at the fourth port **92**. Accordingly, the parallel resonator **146**B is a notch filter.

[0141] The RF filter **38**B is tunable to provide the stopband **66** (e.g., in this case, the notch) of the RF filter **38**B on both a high-frequency side of the passband **62** and a low-frequency side of the passband **62**. As in FIG. **4**, the RF filter **38**B in FIG. **13** is provided by the tunable RF filter path **144**B. In order for the RF filter **38**B to be tunable to provide the stopband **66** (e.g., in this case, the notch) of the RF filter **38**B on both the high-frequency side of the passband **62** and the low-frequency side of the passband **62**, the RF filter **38**B includes the cross-coupling capacitive structure CC(B1) and the cross-coupling capacitive structure CC(B2). The cross-coupling capacitive structure CC(B1) has a variable capacitance, and the cross-coupling capacitive structure CC(B2) also has a variable capacitance. The stopband tuning control output **108** is provided to the cross-coupling capacitive structure CC(B1) and the cross-coupling capacitive structure CC(B2) to adjust their variable capacitances and so that the stopband **66** (e.g., in this case, the notch) is transposed to and from the low-frequency side and the high frequency side of the passband **62** provided by the RF filter **38**B. In essence, the cross-coupling capacitive structure CC(B1) and the cross-coupling capacitive structure CC(B2) are connected to introduce factors into an equation describing the relationship between the resonators R(2,1), R(2,2) and the variable coupling coefficients provided by the capacitive structures C(BP1), C(BP2) that allow for the stopband **66** (e.g., in this case, the notch) to be switched to and from the high-frequency side and the low-frequency side of the passband **62** of the tunable RF filter path **144**B.

[0142] Accordingly, the cross-coupling capacitive structure CC(B1) and the cross-coupling capacitive structure CC(B2) are coupled such that the tunable RF filter path **144**B is tunable to provide the stopband **66** (e.g., in this case, the notch) of the RF filter **38**B on both the high-frequency side of the first passband and the low-frequency side of the first passband by varying the first variable capacitance and the second variable capacitance. In this embodiment, the cross-coupling capacitive structure CC(B1) is electrically connected from the fourth port **92** to the resonator R(2,2). The resonator R(2,2) in the tunable RF filter path **144**B is connected closest to the sixth port **96** of the second hybrid coupler **20**. Furthermore, the cross-coupling capacitive structure CC(B2) is electrically connected from the sixth port **96** to the resonator R(2,1). The resonator R(2,1) in the tunable RF filter path **144**B is connected closest to the fourth port **92** of the first hybrid coupler **18**.

[0143] FIG. **14** illustrates different exemplary frequency response curves **60(1)**, **60(2)**, **60(3)** for the frequency response **60** provided by the RF filter circuit **22** shown in FIG. **13**. In FIG. **14**, the frequency response **60** (and the frequency response curves **60(1)**, **60(2)**, **60(3)**) represent S21 and S12 parameters of each of the RF filters **38**A, **38**B (shown in FIG. **13**) individually as a function of frequency. Thus, the two-port S21 and S12 parameter of the first RF filter **38**A is represented by the frequency response **60** (and the frequency response curves **60(1)**, **60(2)**, **60(3)**) in FIG. **14**. Since the second RF filter **38**B is identical to the first RF filter **38**A, the two-port S21 and S12 parameter of the second RF filter **38**B is also represented by the frequency response **60** (and the frequency response curves **60(1)**, **60(2)**, **60(3)**) in FIG. **14**. The two-port S21 and S12 parameter represents the forward and reverse transmission of the RF filters **38**A, **38**B, as a function of frequency.

[0144] In FIG. **14**, the frequency response curve **60(1)** is the frequency response **60** of the RF filter circuit **22** when the variable capacitances of each of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) are set to 50 fF. The frequency response curve **60(2)** is the frequency response **60** of the RF filter circuit **22** when the variable capacitances of each of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) are set to 30 fF. Finally, the frequency response curve **60(3)** is the frequency response **60** of the RF filter circuit **22** when the variable capacitances of each of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) are set to 10 fF. In this example of the frequency response curves **60(1)**, **60(2)**, **60(3)**, the notch **66** is provided on a high-frequency side HFS of the passband **62** because the notch **66** is provided as the passband **62** rolls off on the side provided at higher frequencies. With regard to the frequency response **60**, the high-frequency side HFS may be considered the side at higher frequencies than the maxima **64** of the passband **62**. A low-frequency side LFS of the passband **62** is the side of the passband **62** that rolls off at lower frequencies. With regard to the frequency response **60**, the low-frequency side LFS may be considered the side at lower frequencies than the maxima **64** of the passband **62**.

[0145] Note from the frequency response curves **60(1)**, **60(2)**, **60(3)**, the notch **66** is transposed closer to the low-frequency side LPF as the variable capacitances of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) increases. The notch **66** also becomes shallower as the variable capacitances of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) increases. The variable capacitances of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) can be continued to be increased until the notch **66** is provided on the low-frequency side LFS of the passband **62**.

[0146] For example, the tuning circuit **69** may be configured to place the notch **66** of each of the RF filters **38**A, **38**B on the high-frequency side HPF when an RF communication band **48**A (e.g., an embodiment of the RF communication band **48** shown in FIG. **2**D) is selected as a HB frequency band in order to reduce insertion loss and improve isolation. The RF communication band **48**A is at a higher frequency range than the RF communication band **44**, which in this example is the ISM frequency band. However, when an RF frequency band **48**B (e.g., an embodiment of the RF communication band **48** shown in FIG. **2**D) is selected is selected as a MB frequency band, the tuning circuit **69** may be configured to place the notch **66** on the low-frequency side LFS of the passband **62** in order to reduce insertion loss and improve isolation and improve isolation. As explained with respect to FIG. **13**, the tuning circuit **69** sets the variable capacitances of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) so that the notch **66** is on the high-frequency side HFS and the low-frequency side LFS of the passband **62** of each of the RF filters **38**A, **38**B.

[0147] FIG. **15** illustrates S parameters for the tunable RF diplexer **10** shown in FIG. **13** where the tunable RF diplexer **10** has been provided to center the passband **62** of the first RF filter **38**A, and the second RF filter **38**B in the ISM frequency band is centered around a center frequency of 2.44 GHz. The notch **66** (shown in FIG. **14**) of the first RF filter **38**A and the second RF filter **38**B can be centered in MB/HB frequency bands with center frequencies from 1.7 GHz to 2.9 GHz. In particular, the B7 transmission frequency band is centered at a center frequency of 2.504 GHz. The S(86,88) parameter shows that the transfer response of the tunable RF diplexer **10** remains at around 0 dB except around the ISM frequency band. Accordingly, the tunable RF diplexer **10** is configured to have small insertion losses in the MB/HB frequency bands between the first port **86** and the second port **88**. The S(86,98) parameter shows that the transfer response of the tunable RF diplexer **10** increases to around 0 dB in the ISM frequency band and decreases relatively quickly outside the ISM frequency band. Accordingly, the tunable RF diplexer **10** is configured to have small insertion losses in the ISM frequency bands between the first port **86** and the seventh port **98**. The insertion losses at the center frequency of the B7 transmission frequency band are reduced and the greater isolation is provided at higher HB frequency bands due to the extra filtering provided on the high-frequency side HPF. Note if an MB frequency band is selected that is on the low-frequency side LFS (i.e. below the center frequency of 2.4 GHz of the ISM frequency band), the tuning circuit **69** is configured to adjust the variable capacitances of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) so that the notch **66** (shown in FIG. **14**) is placed on the low-frequency side LFS of the passband **62**. Otherwise if an MB/HB frequency band is selected that is on the high-frequency side HPF, the tuning circuit **69** is configured to adjust the variable capacitances of the cross-coupling capacitive structures CC(A1), CC(A2), CC(B1), CC(B2) so that the notch **66** (shown in FIG. **14**) is placed on the high-frequency side HFS. In this manner, less insertion loss and greater isolation is provided regardless of whether the MB/HB frequency band is on the high-frequency side HFS or the low-frequency side LFS.

[0148] Those skilled in the art will recognize improvements and modifications to the preferred embodiments of the present disclosure. All such improvements and modifications are considered within the scope of the concepts disclosed herein and the claims that follow.

What is claimed is:

1. A radio frequency (RF) diplexer comprising:

a first hybrid coupler;

a second hybrid coupler;

a RF filter circuit connected between the first hybrid coupler and the second hybrid coupler, wherein the RF filter circuit defines a passband and a notch, the RF filter circuit is tunable to provide the notch on both a high-frequency side of the passband and a low-frequency side of the passband; and a phase inversion component connected between the first hybrid coupler and the second hybrid coupler and configured to provide approximately a differential phase shift.

2. The RF diplexer of claim **1** wherein:
the RF filter circuit comprises a first RF filter and a second RF filter;
the first RF filter is connected between the first hybrid coupler and the second hybrid coupler; and
the second RF filter comprises is connected between the first hybrid coupler and the second hybrid coupler, wherein the second RF filter comprises the phase inversion component.

3. The RF diplexer of claim **2** wherein the first RF filter defines a tunable RF filter path, the tunable RF filter path comprises:
at least a pair of weakly coupled resonators;
a first cross-coupling capacitive structure having a first variable capacitance and connected from the first hybrid coupler to one of the pair of weakly coupled resonators;
a second cross-coupling capacitive structure having a second variable capacitance and connected from the second hybrid coupler to an other one of the pair of weakly coupled resonators.

4. The RF diplexer of claim **3** wherein the tunable RF filter path further comprises a notch filter.

5. The RF diplexer of claim **2** wherein the second RF filter defines a tunable RF filter path, the tunable RF filter path comprises:
at least a pair of weakly coupled resonators, wherein the pair of weakly coupled resonators form the phase inversion component;
a first cross-coupling capacitive structure having a first variable capacitance and connected from the first hybrid coupler to one of the pair of weakly coupled resonators;
a second cross-coupling capacitive structure having a second variable capacitance and connected from the second hybrid coupler to an other one of the pair of weakly coupled resonators.

6. The RF diplexer of claim **5** wherein the tunable RF filter path further comprises a notch filter.

7. The RF diplexer of claim **2** wherein:
the first RF filter defines a first tunable RF filter path, the first tunable RF filter path comprises:
at least a first pair of weakly coupled resonators;
a first cross-coupling capacitive structure having a first variable capacitance and connected from the first hybrid coupler to one of the first pair of weakly coupled resonators;
a second cross-coupling capacitive structure having a second variable capacitance and connected from the second hybrid coupler to an other one of the first pair of weakly coupled resonators;
the second RF filter defines a second tunable RF filter path, the second tunable RF filter path comprises:
at least a second pair of weakly coupled resonators, wherein the second pair of weakly coupled resonators form the phase inversion component;
a third cross-coupling capacitive structure having a third variable capacitance and connected from the first hybrid coupler to one of the second pair of weakly coupled resonators;
a fourth cross-coupling capacitive structure having a fourth variable capacitance and connected from the second hybrid coupler to an other one of the second pair of weakly coupled resonators.

8. The RF diplexer of claim **7** wherein the first cross-coupling capacitive structure, the second cross-coupling capacitive structure, the third cross-coupling capacitive structure, and the fourth cross-coupling capacitive structure are coupled such that the RF filter circuit is tunable to provide the notch on both the high-frequency side of the passband and the low-frequency side of the passband by adjusting the first variable capacitance, the second variable capacitance, the third variable capacitance and the fourth variable capacitance.

9. The RF diplexer of claim **8** wherein the first tunable RF filter path further comprises a first notch filter and the second tunable RF filter path further comprises a second notch filter.

10. The RF diplexer of claim **8** wherein:
the first hybrid coupler comprises:
a first port configured to be coupled to an antenna;
a second port configured to be coupled to external circuitry;
a third port coupled to the first RF filter, wherein the first cross-coupling capacitive structure is connected from the third port to the one of the first pair of weakly coupled resonators;
a fourth port coupled to the second RF filter, the third cross-coupling capacitive structure is connected from the fourth port to the one of the second pair of weakly coupled resonators;
the second hybrid coupler comprises:
a fifth port coupled to the first RF filter, wherein the second cross-coupling capacitive structure is connected from the fifth port to the other one of the first pair of weakly coupled resonators;
a sixth port coupled to the second RF filter, wherein the fourth cross-coupling capacitive structure is connected from the sixth port to the other one of the second pair of weakly coupled resonators;
a seventh port coupled to other external circuitry; and
an eighth port configured to be coupled to an impedance termination.

11. A radio frequency (RF) diplexer comprising:
a first hybrid coupler;
a second hybrid coupler;
a first tunable RF filter path comprising at least a first pair of weakly coupled resonators, where the first tunable RF filter path is connected between the first hybrid coupler and the second hybrid coupler and the first tunable RF filter path defines a first passband and a first notch, the first tunable RF filter path is tunable to provide the first notch on both a high-frequency side of the first passband and a low-frequency side of the first passband;
a phase inversion component connected between the first hybrid coupler and the second hybrid coupler and configured to provide approximately a differential phase shift.

12. The RF diplexer of claim **11** further comprising a second tunable RF filter path comprising at least a second pair of weakly coupled resonators, where the second tunable RF filter path is connected between the first hybrid coupler and the second hybrid coupler and the second tunable RF filter path defines a second passband and a second notch, the second tunable RF filter path is tunable to provide the second notch on both a high-frequency side of the second passband and a low-frequency side of the second passband.

13. The RF diplexer of claim **12** wherein the second tunable RF filter path forms the phase inversion component with the second pair of weakly coupled resonators.

14. The RF diplexer of claim **12** wherein the first tunable RF filter path further comprises:

the first hybrid coupler comprises:
  a first port configured to be coupled to an antenna;
  a second port configured to be coupled to external circuitry;
  a third port coupled to the first tunable RF filter path;
  a fourth port coupled to the second tunable RF filter path;
the second hybrid coupler comprises:
  a fifth port coupled to the first tunable RF filter path;
  a sixth port coupled to the second tunable RF filter path,
  a seventh port coupled to other external circuitry; and
  an eighth port configured to be coupled to an impedance termination.

15. The RF diplexer of claim **14** wherein:

the first tunable RF filter path further comprises:
  a first cross-coupling capacitive structure having a first variable capacitance and connected from the third port to one of the first pair of weakly coupled resonators;
  a second cross-coupling capacitive structure having a second variable capacitance and connected from the fifth port to an other one of the first pair of weakly coupled resonators;
the second tunable RF filter path further comprises:
  a third cross-coupling capacitive structure having a third variable capacitance and connected from the fourth port to one of the second pair of weakly coupled resonators;
  a fourth cross-coupling capacitive structure having a fourth variable capacitance and connected from the sixth port to an other one of the second pair of weakly coupled resonators.

16. The RF diplexer of claim **15** wherein:

the first tunable RF filter path further comprises:
  a first bandpass filter formed with the first pair of weakly coupled resonators and configured to provide the first passband;
  a first notch filter connected in series at the third port and configured to provide the first notch;
the second tunable RF filter path further comprises:
  a second bandpass filter formed with the second pair of weakly coupled resonators and configured to provide the second passband;
  a second notch filter connected in series at the fourth port and configured to provide the second notch.

17. The RF diplexer of claim **16** wherein:

the first cross-coupling capacitive structure and the second cross-coupling capacitive structure are coupled such that the first tunable RF filter path is tunable to provide the first notch on both the high-frequency side of the first passband and the low-frequency side of the first passband by varying the first variable capacitance and the second variable capacitance;
the third cross-coupling capacitive structure and the fourth cross-coupling capacitive structure are coupled such that the second tunable RF filter path is tunable to provide the second notch on both the high-frequency side of the second passband and the low-frequency side of the second passband by varying the third variable capacitance and the fourth variable capacitance.

18. The RF diplexer of claim **11** wherein the first tunable RF filter path forms the phase inversion component with the first pair of weakly coupled resonators.

19. The RF diplexer of claim **18** wherein the first tunable RF filter path further comprises:

a first cross-coupling capacitive structure having a first variable capacitance and connected from the first hybrid coupler to one of the first pair of weakly coupled resonators;
a second cross-coupling capacitive structure having a second variable capacitance and connected from the second hybrid coupler to an other one of the first pair of weakly coupled resonators.

20. The RF diplexer of claim **19** wherein the first cross-coupling capacitive structure and the second cross-coupling capacitive structure are coupled such that the first tunable RF filter path is tunable to provide the first notch on both the high-frequency side of the first passband and the low-frequency side of the first passband by varying the first variable capacitance and the second variable capacitance.

RF Energy Harvesting System from Cell Towers in 900MHz Band :

Available RF energy in the ambient or areas close to transmission towers provides an opportunity to harvest that energy. Some of the most prominent sources are FM radio systems ((88-108 MHz, transmitted power few tens of KW), TV Transmission (180-220 MHz, transmitted power few tens of KW), Cell Tower Transmission (10 to 20 W per carrier), Wi-Fi (2.45GHz, 5.8GHz), AM Transmission (540-1600 KHz, transmitted power few hundred KW) and mobile phones (transmitted power 1W to 2W), etc.

Cell towers can be used as a continuous source of renewable energy as they transmit 24 hours. In India cell towers transmit in the frequency range of 869- 890 MHz in CDMA, 935-960 MHz in GSM 900 and 1810-1880MHz in GSM 1800 bands.
It transmits 10 to 20W per carrier; there maybe 3 to 4 carriers and 3 to 4 operators on a single tower or spread over the roof top of buildings. Gain of the cell tower transmitter antenna is typically 17dB. The half power beam width (HPBW) of the antenna in horizontal direction maybe between 60o to 90o and in vertical direction varies between 5oto 10o. Maximum power is received when the receiver is in the main beam. For cell site consisting of transmitting towers of GSM900 band, signal strengths are calculated in Table I at various distances according to Friis transmission equation.

Pr = PtGtGr[=(4 R)]^2

Where,
Pr = Received Power
Pt= Transmitted Power
Gt= Gain of the transmitted Antenna
Gr= Gain of the receiver Antenna
R= Distance between the transmitter and receiver antennas

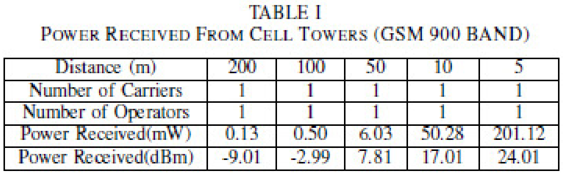

TABLE I
POWER RECEIVED FROM CELL TOWERS (GSM 900 BAND)

Distance (m)	200	100	50	10	5
Number of Carriers	1	1	1	1	1
Number of Operators	1	1	1	1	1
Power Received(mW)	0.13	0.50	6.03	50.28	201.12
Power Received(dBm)	-9.01	-2.99	7.81	17.01	24.01

The gain of the cell tower transmitter antenna is 17dB. Receiver antenna gain is taken as 9dB according to the fabricated microstrip antenna gain. Transmitted power is 20W from the cell towers. Frequency is taken as 950MHz which is approximately middle value of GSM 900 band.
For full signal strength, a cell phone requires only -69dBm power. In a radius within 50m from a cell tower, power level is very high. Such high power levels cause various health hazards, such as, headache, memory loss, nausea, dizziness, tingling, altered reflexes, muscle and joint pain, and ultimately leading to cancer [1].
There are more than 4 lakhs cell towers in India, therefore harvesting ambient RF energy would provide an alternate energy source for various applications and reduce radiation

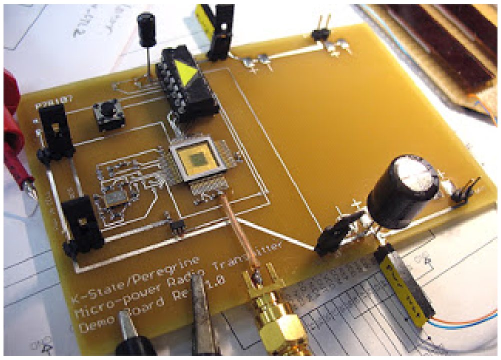
    - RF Energy Harvesting System from Cell Towers in 90...

health hazards. Fig.1 shows the basic block diagram of RF Energy harvesting system.

However, harvesting energy from them poses several challenges.

1. Available power varies with distance, direction and gain of the receiver antenna; therefore high gain antenna for all frequency bands would be required.



2. Due to non-linear dependence of the rectifier impedance on the frequency and power, broadband impedance matching network is essential for maximum power transfer.

3. High efficiency of RF-DC conversion and low power DCDC converter is required.

Minimum numbers of components are used in the design of the RF Energy harvesting system to reduce power dissipation in the circuit itself.

II. MICROSTRIP ANTENNA DESIGN

Antenna is one of the most crucial components in RF energy harvesting system to extract maximum power. Various antenna topologies have been reported in [2-4] for RF energy harvesting but high gain and bandwidth have not been achieved simultaneously.

In this paper, broadband electromagnetically coupled Square microstrip antenna (SMSA) [6] is used for the proposed RF energy harvesting system. It uses stacked multi-resonator configuration for broadband operation. Only the bottom patch is fed and top patch is coupled electromagnetically.

Antenna has a stacked configuration. Two 2mm thick aluminum radiating patches are electromagnetically coupled through an air gap of 1.3cm. First and second square patch are of length 15.2cm and 12.8cm respectively. The ground plane size is 24 cm X 24 cm. The total height of the antenna is 2.6cm. Fig. 2 shows fabricated electromagnetically coupled SMSA designed for GSM 900 band using IE3D software from Zeland.

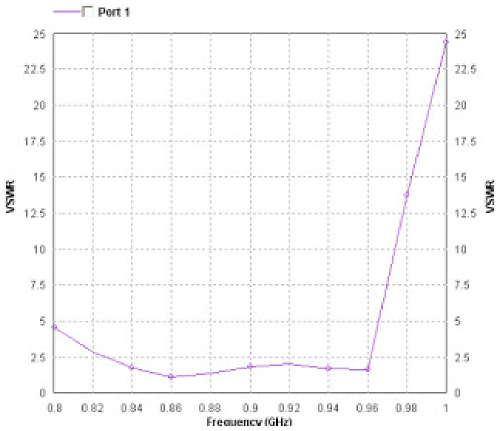
Simulated VSWR and input impedance plots of electromagnetically coupled SMSA are shown Fig. 3(a) and (b).

Bandwidth for VSWR less than 2 is from 877 to 998 MHz

Fig.4 shows the gain plot of the antenna. The gain of antenna is 9.1 dB. Fig.5 shows measured VSWR plot and input impedance plot of SMSA. The antenna is designed for the 935-960 MHz (GSM 900) band but it can also covers part of CDMA transmission band (869-890MHz).To enhance the gain, array of SMSA can be used.

III. RF TO DC CONVERSION USING SCHOTTKY DIODES

A voltage doubler is designed using Dickson Multiplier topology. Silicon based Schottky diode having threshold voltage of 230 mV and diode capacitance of 0.26 pF is chosen.



(a) VSWR of Electromagnetically Coupled SMSA
(b) Input Impedance of Electromagnetically Coupled SMSA

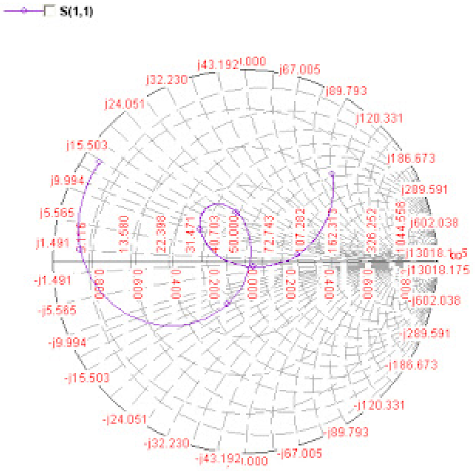


Fig. 3. Simulated (a) VSWR and (b) Input impedance of Electromagnetically Coupled SMSA

At microwave frequency, the non-linear capacitance of the diode governs the maximum power transfer to the load and amplitude of the rectified output as input impedance of the rectifier changes with frequency. Fig. 6 (a) and (b) shows a single stage voltage doubler and 6 stage voltage doubler. Both single stage and 6 stage voltage doubler circuits are fabricated. Fig.7 (a) and (b) show fabricated single stage voltage doubler and 6-stage voltage doubler circuits respectively. Six-stage voltage doubler is implemented to measure the power dependence of the rectifier for lower power level as the voltage measured at single stage is very low. Single stage voltage doubler is used for rectenna measurements inside the lab and near the cell towers as the power level are higher at

these places.

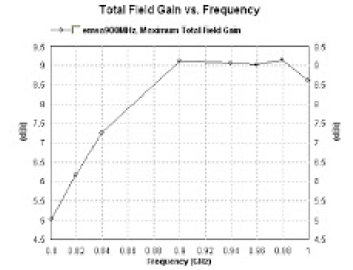

Fig. 4. Simulated gain plot of electromagnetically coupled SMSA

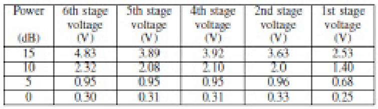
TABLE II
VOLTAGE AT VARIOUS STAGES OF SIX STAGE RECTIFIER WITH 2.2 KOHM LOAD AT 900 MHZ FOR DIFFERENT INPUT POWER LEVELS



Power (dB)	6th stage voltage (V)	5th stage voltage (V)	4th stage voltage (V)	2nd stage voltage (V)	1st stage voltage (V)
15	4.83	3.89	3.92	3.63	2.53
10	2.32	2.08	2.10	2.0	1.40
5	0.95	0.95	0.95	0.96	0.68
0	0.30	0.31	0.31	0.33	0.25

Input impedance of the diode changes with the input poweras the dc operating point of the I-V curve moves in a nonlinear fashion [5]. The impedance variation of a six stage rectifier at 900 MHz with change in power level is shown in Fig.8. Impedance variation is taken at 900MHz as it is the approximate middle value of the CDMA and GSM 900 bands. Large variation of input impedance with input power and frequency makes designing a broadband conjugate matching network complex. Therefore, a resistive impedance matching network, as shown in Fig.9, is used to allow maximum power transfer.

The value of Rmatch depends on the input impedance of the antenna. This approach provides an approximate and simple matching between the antenna and rectifier.

The 6- stage rectifier is tested for its performance by feeding it directly from a RF source. Table II shows output voltage variation of six stage voltage doubler with 2.2 Kohm load at 900 MHz using a RF source at various power levels. Table III shows the output voltage variation of six stage voltage doubler for no load condition.

Rectenna is a combination of rectifier and antenna. Fig.10. shows the experimental setup of rectenna. It consists of an RF source transmitting 900 MHz (approximately middle value of CDMA and GSM 900 band) with output power of 17dBm (50mW). A horn antenna with a gain of 11dB is connected to the RF source to simulate cell towers inside the lab, and voltages at output of rectenna at various distances are measured.

Table IV summarizes the measured results at 900MHz using a single stage voltage doubler with 100K ohm and 10uF load.

Fig. 7. Fabricated (a) Single stage and (b) 6 stage voltage doubler circuit

IV. MEASUREMENT AT ACTUAL SITE

Voltage levels are measured at actual site consisting of transmission cell towers at Indian Institute of Technology Bombay (IIT-B) using the fabricated electromagnetically coupled microstrip antenna and single stage voltage doubler. Figs.11 and 12 show the experimental setup for rectenna measurement at 50 m and 10 m from cell towers respectively. The voltage obtained at 50 m was 0.87V.This voltage can be stepped up using a boost converter. A stand alone boost converter from Texas Instrument TPS61220 has been designed to work from an input voltage of 0.7V. Voltage at 50m after stepping up can be used to charge a battery using a charging circuit. At a distance of 10m voltage of 2.78V is obtained. This large voltage can be used to charge a battery using a charging circuit. The power level observed using a hand-held radiation monitor was 4dBm and 5dBm at 50m and 10m respectively. Lower power levels are observed as the rectenna is not in the main beam of the cell towers antenna.

V. CONCLUSION

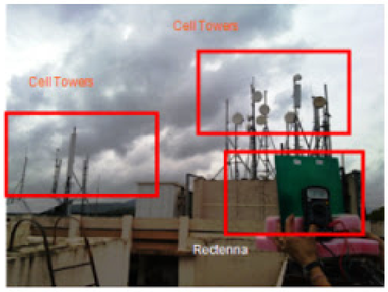

Fig. 12. Experimental setup for Rectenna measurement at 10m from cell tower (IIT-B)

In this article, a RF energy harvesting system from cell towers is presented. A high gain electromagnetically coupled antenna is developed. A silicon based schottky diode single stage and 6 stage rectifier are also designed. A voltage of 2.78V is measured at a distance of 10m from the cell tower. Due to the increase in the population density, many people live within 10m from the cell tower. RF energy harvesting from cell towers would therefore provide two fold benefits: provide an alternative source of energy and protect people living in close vicinity of the tower from radiation health hazards.

Abstract

Energy harvesting or energy scavenging is basically a conversion process of the ambient energy into the electrical energy. The ambient energy exists around us in many different forms including thermal, chemical, electrical and radio frequency (RF). This technique significantly reduces the costs of replacing batteries periodically. Hence, energy harvesting offers various environmental friendly alternative energy sources, which include the vibration, electromagnetic wave, wind energy and solar power. This study will focus on RF energy harvesting that involves the generating of a small amount of the electrical power to drive circuits in wireless communication electronics devices. Recently, wireless sensor network (WSN) has been a crucial part of our daily life. The importance of WSN can be described by the use of sensors in many devices for home security including light sensors, room thermostat and alarm systems. This paper presents an overview and the progress achieved in RF energy harvesting, which involves the integration of antenna with rectifying circuit. Different combinations of antenna and rectifier topologies yield diverse results. Therefore, this study is expected to give an indication on the appropriate techniques to develop an efficient RF energy harvesting system.

Keywords: *Antenna, Rectifier, Energy Harvesting, Wireless Sensor Network*

1. Introduction

In few years back, many new technologies have been applied in order to enhance our life quality. One of these technologies is the cost-saving system in a house which uses self-powered devices. For instance, Figure 1 shows a domestic lighting application which uses a sensor system to operate. The light is automatically turned on once the sensor detects a specific level of darkness in the room. The smart system not only offers a more comfortable living, but also a large scale of energy saving and a lower cost solution.

An energy scavenging method has been applied in small devices based on wireless sensor technology. For instance, battery-less remote control and mobile phone charger which operates using harvested energy is currently having a great demand from users since they contribute to reduce cost and saving time.

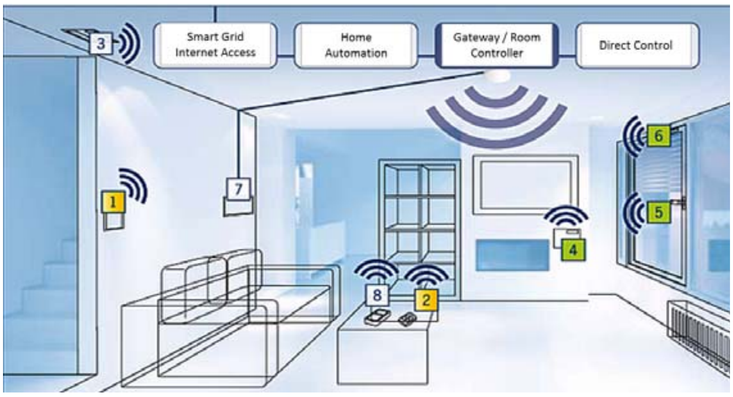

Figure 1. Energy harvesting wireless system in a smart house [1]

In recent years, there has been a growing usage of sensor-based wireless networks and applications which directly leads to the increased battery usage [2]. Until today, the limitation of energy supplies has become a crucial issue for the lifetime of these sensors since they operate on conventional batteries with a limited lifespan and fixed energy rate [3]. Furthermore, the deployment of a large number of sensor nodes results in periodic battery replacements which is impractical and cost-consumed [4].

One of the solutions proposed to overcome these issues is to opt for energy harvesting [3]. Energy harvesting is mostly applied to enhance the efficiency of a system and to enable new technology. Harvesters utilize different radiating sources such as solar, motion and vibration, temperature scale and radio frequency, depending on their type. These different radiating sources are described as in Figure 2 [2] .

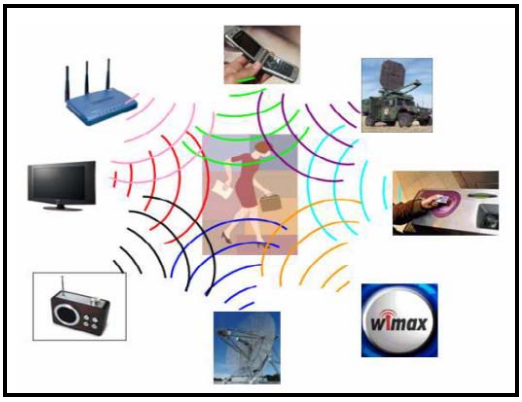

Figure 2. Examples of different radiating sources [2]

Similarly, the ambient energy can be extracted and converted into electrical energy that can be used to power up the sensors. Figure 3 shows the basic block diagram of RF-DC conversion system.

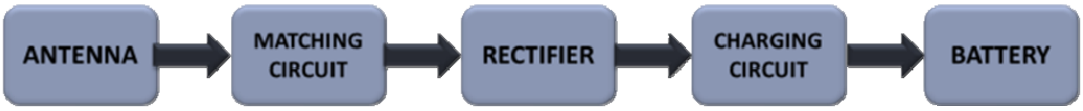

Figure 3. Basic block diagram of RF energy harvesting system

Despite the challenges possessed in RF energy harvesting [5], this system is still preferred due to the increasing availability of free RF energy from the advent of wireless broadcasting and communication systems.

The antenna is the key element of an RF energy harvesting system to capture the radiated RF energy and extract maximum power. The aim is to design antenna which can produce large DC output voltage. Until today, various antenna topologies have been recorded [3][4][6] for RF energy harvesting; nevertheless, only a few achieves a good performance in both gain and bandwidth.

Antennas can be designed in many forms, for instance patch antennas, dipole antennas, planar antennas, microstrip antennas and uniplanar antennas. Several types of patch antennas have been designed in various frequency regions focusing on bandwidth improvement [7]. Patch antenna with spiral structure [8] are also introduced where 3 types of spiral were compared to find the optimal structure.

Printed dipole antennas possess numerous advantages including low cost and large bandwidth. Therefore a dipole antenna was designed for optimum usage in GSM band applications [9]. Another antenna was designed for voltage boosting purposes in order to enhance DC output of RF energy harvesting system, specifically in a weak signal reception environment [10]. A study on improving antenna to exhibit dualband response for the energy harvesting application has been done in [11]. The other researchers are focused mainly on single band applications.

This paper reviews several techniques in obtaining RF energy from the ambient sources to be converted into the DC signal. In particular, the study focuses on the topology of the antennas and rectifying circuits to obtain optimum efficiency of the RF-DC conversion.

2. Energy harvesting system

An energy harvesting system consists of two main subsystems. The first one is the receiving antenna, which functions to capture ambient RF energy to power up the integrated embedded system. The second subsystem is the rectification circuitry, which converts the input RF power into DC output power efficiently.

The antenna captures the RF signals, and subsequently the rectifier circuit extracts the power of those signals and converts them into DC voltage. Therefore, an antenna with high efficiency is needed to transfer wireless power effectively.

2.1. Antenna Design

Recently, several efforts have been given to enhance the efficiency of the antenna in power scavenging [12][13]. Rectifying antenna, or literally called a rectenna, is one of the most important components in the wireless power transmission. It comprises a receiving antenna and a circuit which converts radio frequency to direct current (RF-DC) [14][15][16]. An efficient wireless power transmission system requires a rectenna with high RF-DC conversion efficiency. Several antenna topologies have been reported [5] for RF energy harvesting.

Most early research on radio frequency (RF) energy harvester designs focus on harvesting RF energy in a single RF band [17][18]. However, recently, there have been designs and implementations of a dual band [11] and triple band [19][6] antenna design for RF energy harvesting applications. The design of compact multiple band microstrip antennas for wireless applications also gains a highlight and received much attention in [20][21].

The planar monopole antenna is used to provide required impedance matching at two bands with easier integration [11]. The antenna consists of a ground plane on the back of the PCB, and three connected microstrip lines on the top of the PCB. All the microstrip lines shared the same feeding point with the RF input pin. The antenna was optimized by altering the length of the microstrip lines which also managed to provide required impedance. The same antenna structure with different antenna parameters was also designed. The purpose is to use the antenna for different implementations where Antenna A is for 900MHz & 1900MHz band application while Antenna B is for 900MHz & 2000MHz band application. Antenna B obtained better return loss with -35dB in comparison to Antenna A with -25dB of return loss. However, both antennas are still suitable to be adapted to general dual band applications which require a matching to different impedances at two frequencies.

Another study on dual band antenna has been done, but this time a microstrip patch was used [22]. The structure consists of a square-shaped ring patch and it is connected to a microstrip feedline. This antenna potentially work well with RF energy harvesting system due to its promising gain and bandwidth values. Furthermore, miniaturized microstrip antennas are able to improve their performance and reduce the overall size of wireless devices [27].

The study about ring patches proves that various ring shapes managed to obtain better bandwidth and higher radiation resistance when the higher order modes are excited [23][24][25]. Another different study found that the ring antenna is excited with a capacitive strip in another layer in a stacked configuration [26]. Paper [25] describes the impedance properties of a dual frequency concentric annular ring microstrip patch antenna. Meanwhile, a parametric study of a microstrip square ring antenna has been done in [22]. From the investigation, the bandwidth and gain of the microstrip square ring antenna increased with the increment the ring’s width even though the resonance frequency is slightly shifted to a lower frequency.

Printed dipole was also a type of antenna that was used for energy harvesting due to its advantageous features such as low cost and provide large bandwidth. In [9], printed dipole antenna is designed and optimized specifically for GSM band application at 915 MHz. This antenna yields a very omnidirectional radiation pattern which is very suitable for RF energy harvesting to capture signals in all directions. A mini reflector was used to triple up the gain of this antenna from 2.49 dB to 6.28 dB.

In [8], several spiral antennas for RF energy harvesting in 0.2 GHz to 2.4 GHz frequency range is compared. The spiral was known as one kind of antenna structure that possess radiation pattern over a wide range of frequency. However, it has less packing conformity when built in printed circuit board, which caused a drawback of many excessive areas on the board. 3 types of spiral antennas have been compared which are Archimedean spiral antenna, square spiral antenna and hexagonal spiral antenna as shown in Figure 4.

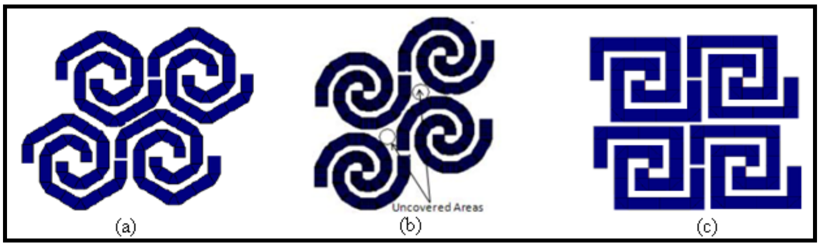

Figure 4. Array for (a) Hexagonal spiral antenna (b) Archimedean spiral antenna (c) Square spiral antenna [8]

Archimedean and square spiral antenna obtained better gain value than hexagonal spiral antenna with 5dB and 4.8dB, both at 2.4GHz frequency. However hexagonal spiral tends to approach the circular shape which optimizes the PCB cover area by accommodating a number of spirals. It also generates better broadband while maintaining packing conformality.

Patch antenna most likely has been chosen to be designed and implemented with RF energy harvesting. Various structures in the form of patch antennas have been designed such as L-shape, U-shape, star shape, E-shape, circular patch and square shaped to be used in the 900MHz, 2.4GHz, 4GHz, 5GHz, and 6GHz frequency [28][29][30][31]. Despite of its advantages of being low profile and inexpensive to fabricate, patch antennas has a drawback of narrow bandwidth, low efficiency, and low gain [7][4][19]. In order to overcome the problem, some methods have been investigated and proposed. These include embedding slots on the patch antenna and using various impedance matching and feeding techniques [32][33][34].

Antenna array design has also been investigated for RF energy harvesting with expectations to scavenge power effectively in [12][13]. Author of paper [4] proposed a microstrip stacked patch antenna array with lower power consumption. It shows better VSWR, return loss and efficiency compared to common inset fed patch antenna at 2.45 GHz frequency with improvement of return loss of about 30dB. Apart from that, the high gain value of 11.98 dB also was a factor that contributes to the antenna's ability to achieve better voltage levels. However this antenna has a drawback of larger antenna size even though the use of antenna arrays can increase the RF and DC power [2]. A single patch itself has a dimension of 40.49mm x 40.49mm.

2.2. Rectifier Design

Rectifier, which is also called as pump device, has the function of converting an input RF signal received by the antenna into suitable DC supply voltage. Rectifier converts a part of the incoming power supply to DC for power supply. It takes advantage of the diode's behavior to rectify a signal; depending on the signal level, the diode allows or does not allow the current to pass.

The basic or simplest rectifier consists of two different positions of the capacitor; parallel or series. Figure 5 (a) shows a rectifier using a series diode where the capacitor is connected in series followed by a parallel connected diode.

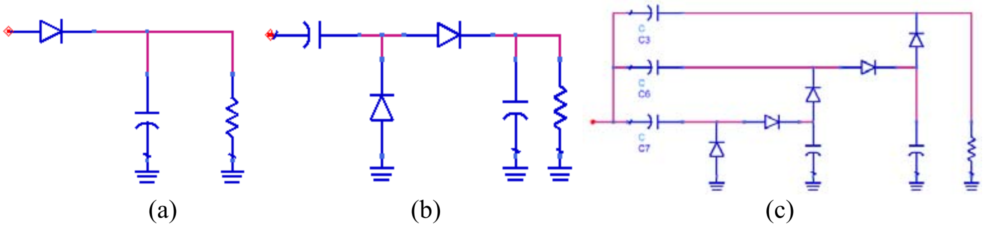

Figure 5. Type of rectifier: (a) Basic rectifier (b) Voltage doubler (c) Voltage multiplier

From the basic rectifier, a voltage doubler circuit can be designed by using two diodes and two capacitors as shown in Figure 5 (b). The voltage doubler configuration is chosen to be used as the rectifier circuit in [35] and [36]. Paper [37] has used conventional voltage doubler rectifier together with floating-gate voltage doubler rectifier. The function of voltage doubler rectifier is to rectify the full-wave peak-to-peak voltage of the incoming RF signal. It can be arranged in cascade to increase the output voltage.

Additional sections of diodes and capacitors may be cascaded in order to obtain voltage multiplier circuits of higher order. Voltage multiplier consists of N-stage which indicates the number of stages of particular voltage multiplier. Figure 5 (c) shows the design of a voltage multiplier.

The design of voltage multiplier circuit has been described in various literatures [38][39][40], for instance Cockroft Walton, Villard Cascade and Dickson voltage multiplier. Cockroft Walton voltage multiplier is capable to produce DC output voltage potential tens of times that of the peak AC input voltage. However, the drawback of this kind of rectifier is the limitation in current capacity and regulation. Table 1 shows the comparison of the rectifiers.

Table 1. Comparison of rectifiers

Type of rectifier	Structure	Rectifier Topology
Basic rectifier	A diode connected in series with a load. A capacitor acted as a filter to smoothen the ripple in the output. Commonly called as single-stage rectifier.	Half-wave rectifier, full-wave rectifier
Voltage doubler	Uses two stages to approximately double up the DC voltage.	Villard circuit, Greinacher circuit, bridge circuit, Dickson charge pump voltage-doubler
Voltage multiplier	Converts RF energy into DC voltage using a network of capacitors and diodes.	Villard cascade voltage multiplier, Dickson multiplier, Cockroft Walton voltage multiplier

3. Discussion

The integration of the antenna and the rectifier is also known as rectenna. The rectenna is a passive element with a diode than can receive and rectify microwave power to direct current, which results in its ability to operate without any power source. Many research works on rectenna elements have been published. For example, the finding of various antenna types to be used in rectenna system such as dipole, Yagi-Uda antenna, microstrip antenna, monopole, coplanar patch, spiral antenna, and even parabolic antenna. The antennas can also be integrated with any type of rectify circuit (rectifier) such as single shunt full-wave rectifier, full-wave bridge rectifier, voltage multiplier and hybrid rectifiers. The circuit, especially the diode, determines the RF-DC conversion efficiency. Common diode used in most rectennas is silicon Schottky barrier diodes.

RF energy harvesting basically has several different types of system. In [2], two systems have been studied to recover the RF energy which is a broadband system and a narrowband system. For both systems, a broadband antenna is needed and therefore a spiral antenna is used. Unlike any spiral antenna structure in [8], an equiangular spiral antenna in [2] is used due to its advantageous features including possible dual polarization and its ability to operate under a broad frequency band.

In broadband system, it consists of rectifier without matching circuit and broadband antenna. Therefore the antenna used must be able to maximize the DC power harvested and recover all signals available. For that purpose, an omni-directional broadband antenna is needed. Return loss of the proposed antenna is lower than -10dB which means the efficiency of this antenna will be more than 90% overall. The antenna also managed to obtain a quasi omni-directional radiation pattern at a frequency of around 1GHz.

While for the narrowband system, the same antenna structure was used together with matching circuit which resulted an increment to DC power. However, the drawback of this system is the low efficiency of conversion RF/DC that occurred (0.6%).

Another paper that is interested in spiral antenna as a receiver medium is stated in [37][38]. It presents a constant gain and input impedance in the interest band with circular polarization. The input recoverable power increases increasing the antenna gain. Antenna gain plays an important role on the RF to DC conversion efficiency. In addition, the antenna with directional radiation pattern contributes higher gain achievement, which eventually will increase the antenna's receiving power. Therefore, most researchers use array and stacked patch antenna technique to increase the antenna gain, approximately until 10dB and above.

Several designs of antenna that are operate under a broad frequency band haven been identified from selected sources. These antennas have been redesigned and optimized using Computer Simulation Tool (CST). Some modifications have been made to the antenna structure to investigate the new outcome. Most of the antenna uses a FR-4 board material with different type such as microstrip, monopole, dipole and planar and embedded with various antenna structure as summarized in Table 2.

Table 2. Comparison of antenna structure

Antenna Type	**Antenna Structure**	**Remarks**	**Ref.**
Monopole	Microstrip line	• Well suited to be adapted to general dual band applications. • Has a flexible design where required impedance can be achieved by altering length and geometries of the microstrip lines. Return loss achieved is -25dB. • Helps provide the ability to operate at more RF bands and harvest energy for remote power applications.	[14]
Microstrip	Square ring	• This antenna has a drawback of a very narrow bandwidth. • Bandwidth increased by increasing the width of the ring, however, another drawback is resonant frequency is also slightly shifted to lower frequency when the width of ring increases. Therefore only the width of two sides away from the feedline is increased with return loss achieved until -44.8dB and a gain of 6.12dB.	[29]
Dipole	Similar to golf clubs shape	• The structure of suggested GSM printed dipole antenna is geometrically optimized to reduce antenna size, increase impedance adaptation, to center the resonant frequency and to increase gain. • Have an omnidirectional radiation pattern which is very good for energy harvesting antenna. • Antenna gain is improved by 252% by using a mini reflector behind the antenna at a distance of $\lambda/4 \approx 75$mm.	[12]
Planar	Spiral	• The rectangular patch antenna has a drawback of narrow bandwidth. However, instead of that, it has good radiation pattern over a wide range of frequency. 3 types of spiral antenna is compared – Archimedean spiral, square spiral, and hexagonal spiral. • Among all 3 designs, hexagonal spiral generates better broadband and gain. More number of spirals also can be used by using hexagonal spiral.	[11]
Microstrip	Rectangular	• Patch antenna has the advantages of low profile and suitable for high-frequency application despite of their narrow bandwidth. • Antenna structure has a patch, pi matching network, and partial ground plane on the other side. The edge fiddling technique is used. • Wide bandwidth can be achieved by adjusting antenna's parameter.	[8]
Planar	Stacked patch with	• Antenna consists of two stacked rectangular patches and a ground plane where the upper four patches have four slots	[3]

	slots	on the edges. • The antenna has a drawback in terms of size. It is bigger than other conventional antenna for RF energy harvesting. • However, it has a very high gain value of 11.98dB.	
Microstrip	Equiangular spiral	• For maximal power transfer, the antenna impedance must be matched to the optimal diode impedance for all frequencies. • Equiangular antenna has a possible dual polarization, broadband antenna and omni-directional radiation pattern.	[1]

There are a few requirements need to be considered when designing a rectifier circuit [41]. For instance, several criteria of rectifying circuit are evaluated in [42] including the choice of diodes, number of stages, effect of load impedance as well as the efficiency of RF-DC conversion.

We need to bear in mind that the most crucial requirement for a harvesting energy circuit is to be able to operate with weak input RF power. Therefore, a diode with a very fast switching time need to be used for the energy harvesting circuit is operating at high frequencies. Schottky diode is one of the popular diodes used in rectifier circuit. It uses a metal-semiconductor junction which allows the junction to operate much faster and gives forward voltage drop. Saturation current is another critical parameter that impacts the efficiency of diodes.

The number of rectifier stages has a major influence on the output voltage of the energy harvesting circuit where the output voltage is directly proportional to the number of stages used in the energy harvesting circuit. A rectifier with too few rectifier stages would yield an insufficient output voltage while too many rectifier stages may damp out the effect of the high Q-resonator. Figure 6 and Figure 7 shows the relation of number of rectifier stages on the energy harvesting efficiency and output voltage.

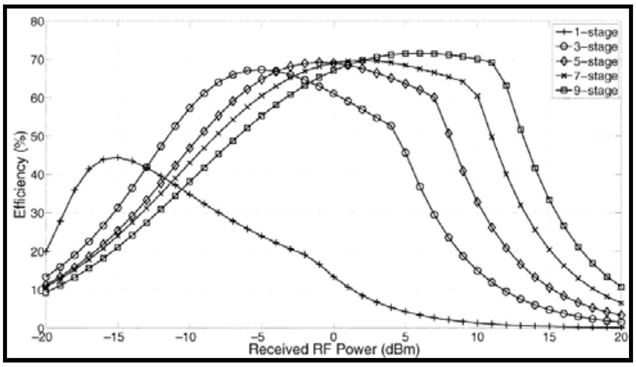

Figure 6. Effect of number of stages on the efficiency of energy harvesting circuit [42]

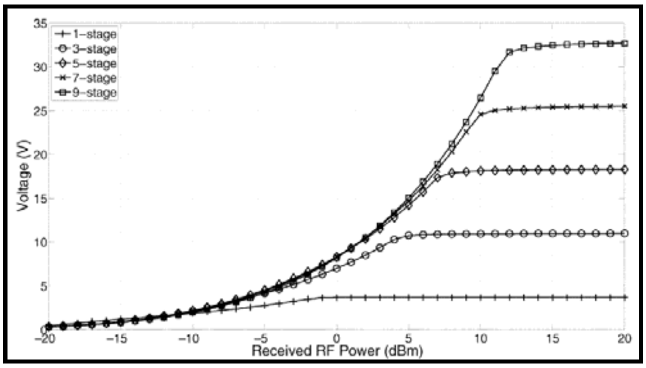

Figure 7. Effect of number of stages on the output voltage of energy harvesting circuit [42]

As mentioned previously, there have been several types of system in RF energy harvesting. Researchers in [2] came out with two types of systems. The first one is a broadband system without using any matching circuit while the second one is a narrowband system which includes a matching circuit.

The DC power scavenged using the narrowband system [2] can be attended until 400pW. The RF/DC converter used is a voltage doubler which uses the harmonic balance method. It was then optimized by using a commercial zero biased Schottky diode. Figure 8 shows the variations of the output DC power versus the input RF power at 1.5GHz which resulting the RF power more than -32dBm for both simulation and measurement.

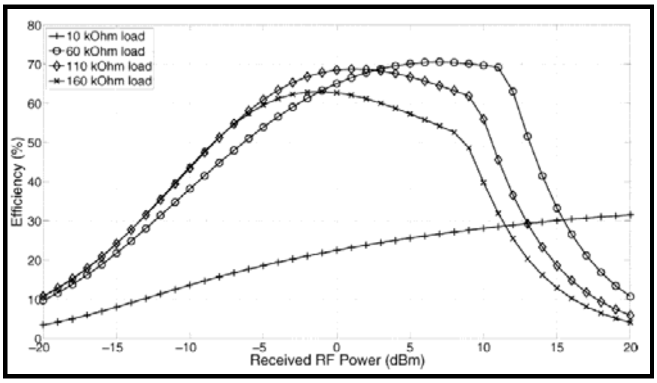

Figure 8. Effect of load impedance on the efficiency of energy harvesting circuit [42]

Based on the review gained in this study, it is believed that there is still a room for further researches and developments before the technique become mature. Thus, it is recommended to further investigate and discover the optimum antenna and rectifier topology at GSM850, GSM900, GSM1800 and ISM frequency band particularly in Malaysia. It also involves designing several types of antennas to cover the above-mentioned frequency range in order to match the criteria for the overall system.

For the RF energy harvesting, the antenna with directional radiation pattern is most suitable to integrate with rectifying circuit because it radiates or receives more power in particular directions. However, antennas with an omnidirectional radiation pattern can still be considered since it provides and receives equal signals in all directions even though the signal strength might be weaker. Another factor to consider is to design an antenna with higher gain since the gain relates to the antenna's ability to capture ambient signals significantly. Besides, the antenna itself must have a return loss better than -10 dB which contributes to 90% of antenna efficiency. Larger return loss indicates higher power being radiated by the antenna which eventually increases the antenna's gain. Therefore, printed circuit board or PCB-based antenna will be used in this project since it is easy to fabricate, low cost and able to achieve high gain.

While the optimum rectifying circuit topologies must be comprehended to fulfill the requirement of supplying sufficient energy harvested and thus, it has been recognized that voltage multiplier is capable to realize a maximum conversion of RF signal into DC electrical signal.

Figure 9 shows the measurement setup for an energy harvesting system. The propagation model as studied in [43] can also be used to determine the path loss between the transmitter and receiver. Then, the intelligent technique developed by [44] is suggested to be applied in this work to improve the energy-efficiency for wireless sensor networks.

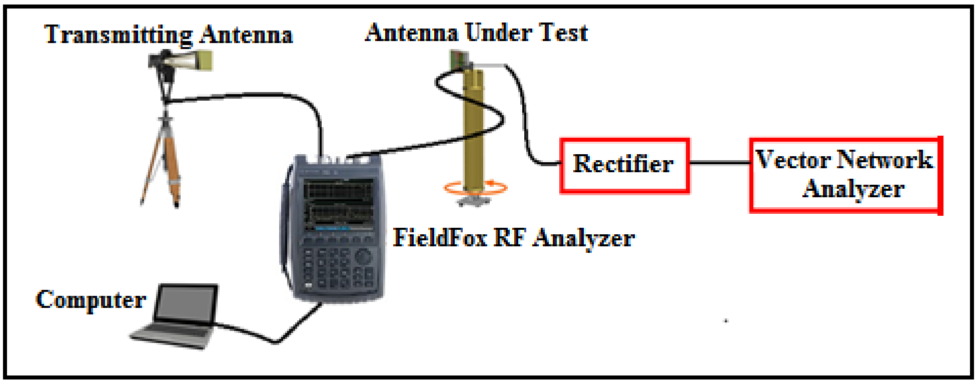

Figure 9. Antenna and rectifier measurement setup

4. Conclusion

A study on energy harvesting based on microwave signals has been reviewed. There are some design issues occurred in RF energy harvesting that need to be considered including low conversion efficiency and low rectified power. Improvements in efficiency of the RF signal harvesting is important. In general, many published papers on RF power to DC conversion - have presented circuits that are capable of converting input or incident power as low as -20dBm. This means that, if an RF survey or scan finds signals in space, with power spectrum levels around -20dBm, then it is potentially viable to harvest such signal power. The verification process of the proposed antenna and rectifier design that operates particularly in GSM and ISM band will be further explored and implemented through an experiment in laboratory and field works. It is believed that these discoveries will motivate further researches towards the usage of RF energy harvesting particularly in wireless sensor networks and their applications.

Abstract

A low profile design which could be used in order to analyze RF energy in near home premises is presented in this paper. The system design is intended to practice in the real world in an easy, economical and DIY way. The idea was to detect the possible source of RF energy that could be harvested even for a short span. A monitoring unit which is microcontroller with two patch antennas, each with a two stage schottky diode voltage multiplier acting as its sensors look for a potential RF energy (Bi-directional only) as soon unit powered up, then unit compare and record the strength of nearby RF energy which is provided as feedback to a servo motor. A rectenna, which is mounted on the top of the servo motor, is made responsible to measure and harvest RF energy. The DC power from the harvesting rectenna is used to power digital thermometer with an LCD module. A low profile prototype is implemented, tested locally and found with acceptable performance.

Keywords: *Energy harvesting, Measurement, Rectennas, Schottky diode, Sensor System.*

---

1. Introduction

Emerging self powered systems challenge and dictate the direction of research in energy harvesting (EH). State of the art in energy harvesting is being applied in various fields using different single energy sources or a combination of two or more sources. This kind of environmental friendly energy sources include energy harvesting from rectennas, passive human power, wind energy and solar power. Power we can extract from those techniques is limited by regulations and free-space path loss. As a general idea, small dimensions are a basic feature of portable devices, so the rectenna should be the same way. [17] Smaller the size results in the received power to be lower. This made wireless power transfer suitable for the low-power applications, e.g., a low-power wireless sensor.

The way technology advance every year allow the decrease of certain characteristics in digital systems, like size and power consumption, that will lead to the gain of new ways of computing and use of electronics, as an example we have wearable devices and wireless sensor networks. Currently, these devices are more powered by batteries, however, they present many disadvantages such as: the need to either replace them or recharge them periodically and their big size and weight compared to high technology electronics. A solution proposed to this problem was stated before: to extract (harvest) energy from the environment to either recharge a battery, or even to directly power the electronic device. [3][20]

Targeted RF energy is in the ambient or areas close to transmission towers provides an opportunity to harvest that energy. Some of the most prominent sources are FM radio systems ((88-108 MHz, transmitted power few tens of KW), TV Transmission (180-220 MHz, transmitted power few tens of KW), Cell Tower Transmission (10 to 20 W per carrier), Wi-Fi (2.45GHz, 5.8GHz), AM Transmission (540-1600 KHz, transmitted power few hundred KW) and mobile phones (transmitted power 1W to 2W), etc. [15] Cell towers can be used as a continuous source of renewable energy as they transmit 24 hours.

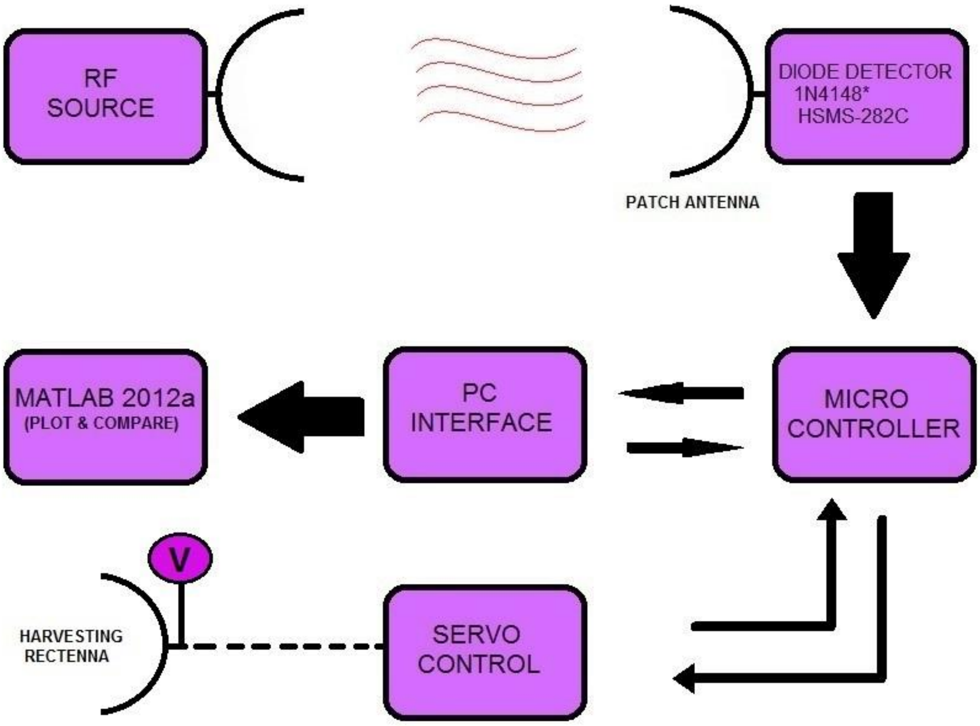

Fig. 1: a) Detailed Block Diagram for proposed system. (V-voltmeter)

Fig 1 presents the basic functionality of the system:

1. First, an antenna is in charge to capture the RF signals from the possible source of interest (CDMA-GSM Band).
2. Then a zero bias diode detector circuit (voltage multiplier) will convert RF-DC (carrier power) which will be input to the monitoring unit.
3. The Arduino Uno (open source hardware as monitoring unit) is used to read real time analog data from the voltage multiplier and will send it to PC via an interface.
4. Matlab R2012a software is used to read digital data values available at pc port and to plot it in terms of voltage, compare the signal and put command to control servo motor of the measuring Rectenna.
5. Servo motor will get a command from Matlab R2012a via microcontroller unit and also sent back feedback voltage for current position.
6. Finally the measuring rectenna will be on target RF source to measure electric field strength and display it in terms of voltage on the voltmeter.

Several operating frequencies for the rectenna have been investigated in the literature. Traditionally the GSM900 band has been utilized due to the presence of 2G networks; additionally the 1800 MHz band has also been considered which implies a smaller antenna aperture area than that of 900MHz. Both frequency bands present similar advantages because they have comparably low atmospheric loss, cheap components availability, and high conversion efficiency.[4][8] Hence the frequency bands corresponding to mobile telephone systems such as 800 MHz, 900 MHz and 1800MHz present good alternatives for electromagnetic energy harvesting systems, although they require a larger antenna size.

2. Design

In order to be able to utilize wireless power efficiently rectenna is needed. This paper presents a rectenna system with numerical and test observations. This provides a good insight of low profile system for the wireless power assessment and utilization. The incident RF power is converted into dc power by the voltage multiplier. The matching network, composed of inductive and capacitive elements, ensures the maximum power delivery from antenna to voltage multiplier. The energy storage (output capacitor) ensures smooth power delivery to the load and as a reserve for durations when external energy is unavailable. Such a design needs to be carefully crafted: increasing the number of multiplier stages gives higher voltage at the load, and yet reduces the current through the final load branch. [17]

This work has three major goals:

1. Measurement of stray radiation in term of Electric field intensity (V/ m).
2. RF energy harvesting/recycling.
3. Powering of low-power applications.

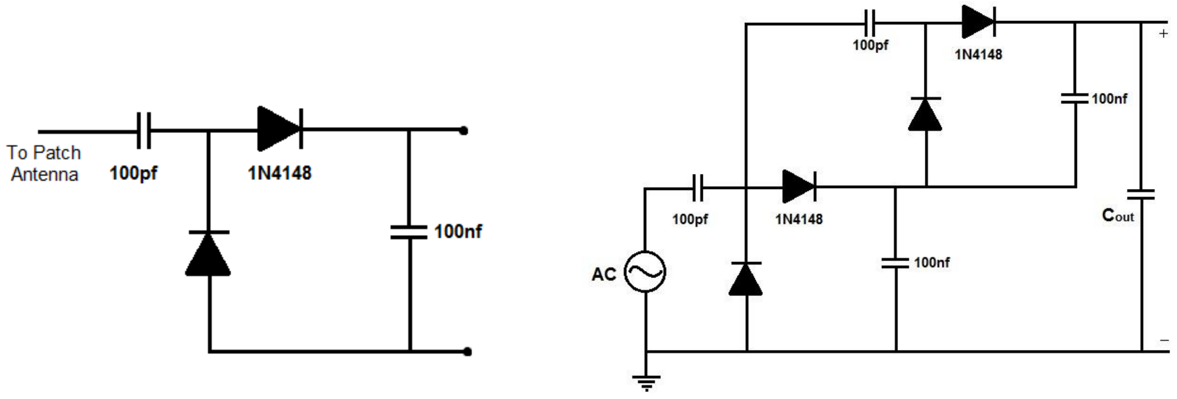
2.1. Voltage multiplier and diode selection

The forward voltage drop (V_f), reverse-recovery time (T_{rr}), and junction capacitance (C_j) of Schottky diodes are closer to ideal than the average “rectifying” diode. This makes them well suited for high-frequency applications. Unfortunately, though, Schottky diodes typically have lower forward current (If) and reverse voltage (V_{rrm} and V_{dc}) ratings than rectifying diodes and are thus unsuitable for applications involving substantial amounts of power, Though they are used in low voltage switching regulator power supplies. [23]

The Schottky diodes used are characterized by a low parasitic capacitance C_{jo} (0.14 pF) and a low serial resistor R_s (20 Ω). At microwave frequencies, rectifiers are highly nonlinear and difficult to design based upon purely analytic equations. Commercially available harmonic-balance simulators are useful at low power levels.

When looking for a rectifying diode in the context of RF recycling, a diode with high conversion efficiency, even for very small incident power levels is required. One of the crucial requirements for the energy harvesting circuit is to be able to operate with weak input RF power. For a typical 50-ohm antenna, the -20 dBm received RF signal power means amplitude of 32 mW. As the peak voltage of the ac signal obtained at the antenna is generally much smaller than the diode threshold [12], diodes with lowest possible turn on voltage are preferable. Moreover, since the energy harvesting circuit is operating in high frequencies, diodes with a very fast switching time need to be used. [17] Schottky diodes use a metal–semiconductor junction instead of a semiconductor–semiconductor junction. This allows the junction to operate much faster, and gives a forward voltage drop of as low as 0.15 V.

Earlier the choice was using Fairchild’s 1N4148 small signal diodes and 1N5819 Schottky rectifiers. But the study presented in [22] gave a broad view of there operation under various condition determine that the previous diodes having higher forward voltage requirement as compared to Hsms 282c and the capacitance of the diode’s is higher as well .The final rectifier circuit is designed using Hsms 282c Schottky Diode. Avago’s Hsms-282x family of zero bias Schottky detector diodes are already designed and optimized by manufacturer for use in small signal (Pin >-20 dBm). They are ideal for RFID and RF Tag applications where primary (DC bias) power is not available. [13][14]



a) **b)**

Fig. 2: a) Single stage diode detector. b) Two stage diode detector with output capacitor.

The fig. 2 above presents the two types of diode detectors on of which (b) is full wave rectifier (known also as a two stage diode voltage doubler). Such a circuit offers several advantages. First the voltage outputs of two diodes are added in series, increasing the overall value of voltage sensitivity for the network (compared to a single diode detector). Second, the RF impedances of the two diodes are added in parallel, making the job of reactive matching a bit easier. [14]

The number of rectifier stages has a major influence on the output voltage of the energy harvesting circuit. [17] Each stage here is a modified voltage multiplier, arranged in series. The output voltage is directly proportional to the number of stages used in the energy harvesting circuit. However, practical constraints force a limit on the number of permissible stages, and in turn, the output voltage. Here, the voltage gain decreases as number of stages increases due to parasitic effect of the constituent capacitors of each stage, and finally it becomes negligible.[13]

2.2. Rectenna

The word rectenna is composed of rectifying circuit and antenna. The rectenna and its word were invented by W. C. Brown in 1960's. [2] The rectenna can receive and rectify a microwave power to DC, is passive element with a rectifying diode, operated without any power source. The antenna of rectenna can be any type such as dipole, Yagi-Uda antenna, microstrip antenna, monopole, coplanar patch, spiral antenna, or even parabolic antenna. The rectenna can also take any type of rectifying circuit such as single shunt full-wave rectifier, full-wave bridge rectifier, or other hybrid rectifiers. The circuit, especially diode, mainly determines the RF-DC conversion efficiency; rectennas with FET or HEMT appear in recent years. (The rectenna using the active devices is not passive element). Fig. 4: Modified Inset-feed Patch Antenna with Dimensions a) CAD design with dimension b) Fabricated patch on FR4

A circular polarized microstrip patch antenna in fig 4 a) and b) above (86 mm x 75 mm) has been associated with the rectifier to obtain the complete rectenna design. The antenna simulation was carried out using the electromagnetic simulator Ansoft HFSS v.11 [9]. The closest to desired resonant frequency has been achieved and matched in a single simulation. It showed a good input matching level at 886 MHz.

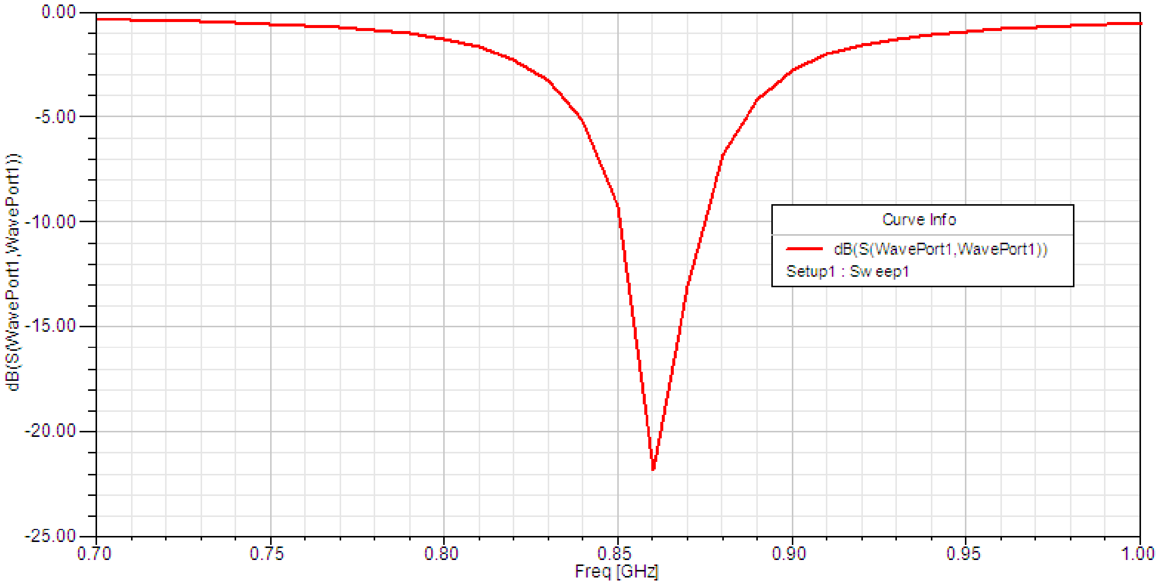

Figure 5: Return Loss (S_{11}) of Microstrip antenna.

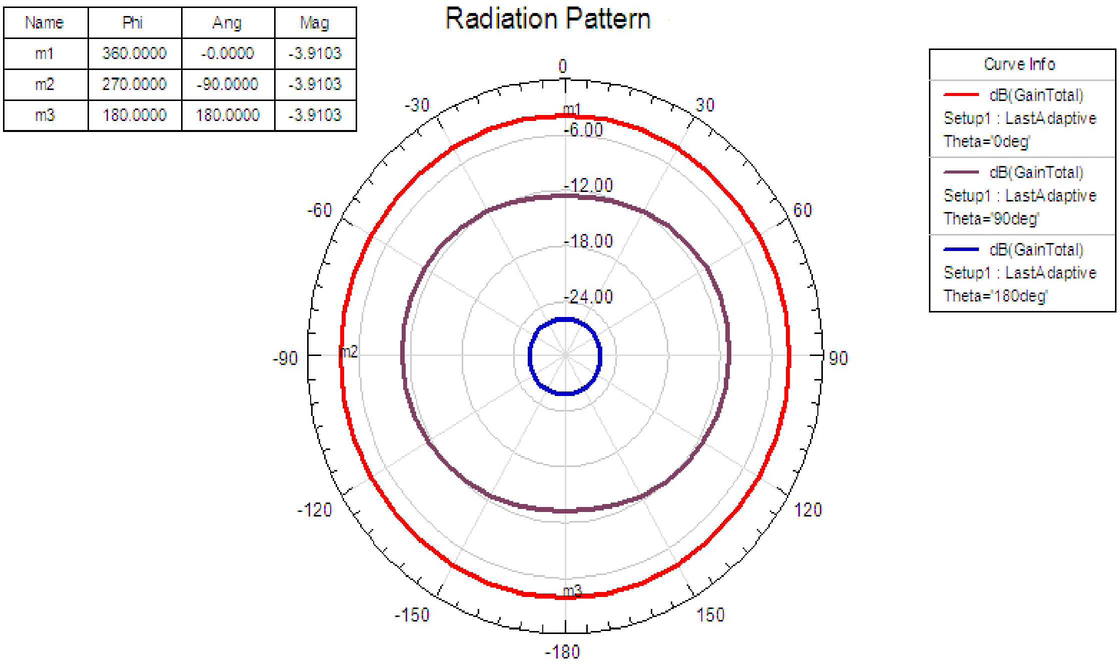


Name	Phi	Ang	Mag
m1	360.0000	-0.0000	-3.9103
m2	270.0000	-90.0000	-3.9103
m3	180.0000	180.0000	-3.9103

Figure 6: Radiation Gain plot of Microstrip antenna.

After simulating the structure figure 5 above showing return loss (S_{11}) of the patch antenna structure .The plot gives return loss of ~21.9 dB at 886 MHz. Figure 6 is the radiation gain plot of the microstrip antenna at 886 MHz from three major angles of 0, 90 and 180 degree which is showing the maximum gain as -3.91dB.Here point t ponder is although the bandwidth of antenna is ~25 MHz still it could be used to beyond that band. The problem that will occur using this antenna beyond its resonant band is mismatched impedance and it will not produce maximum/efficient output.

The purpose of the inset cut in the patch is to match the impedance of the feed line to the patch without the need for any additional matching element. This is achieved by properly controlling the inset position. Hence this is an easy feeding scheme, since it provides ease of fabrication and simplicity in modeling as well as impedance matching. However as the thickness of the dielectric substrate being used, increases, surface waves and spurious feed radiation also increases. The feed radiation also leads to undesired cross polarized radiation. [17][11]

The three essential parameters for the design of a rectangular Microstrip Patch Antenna are:

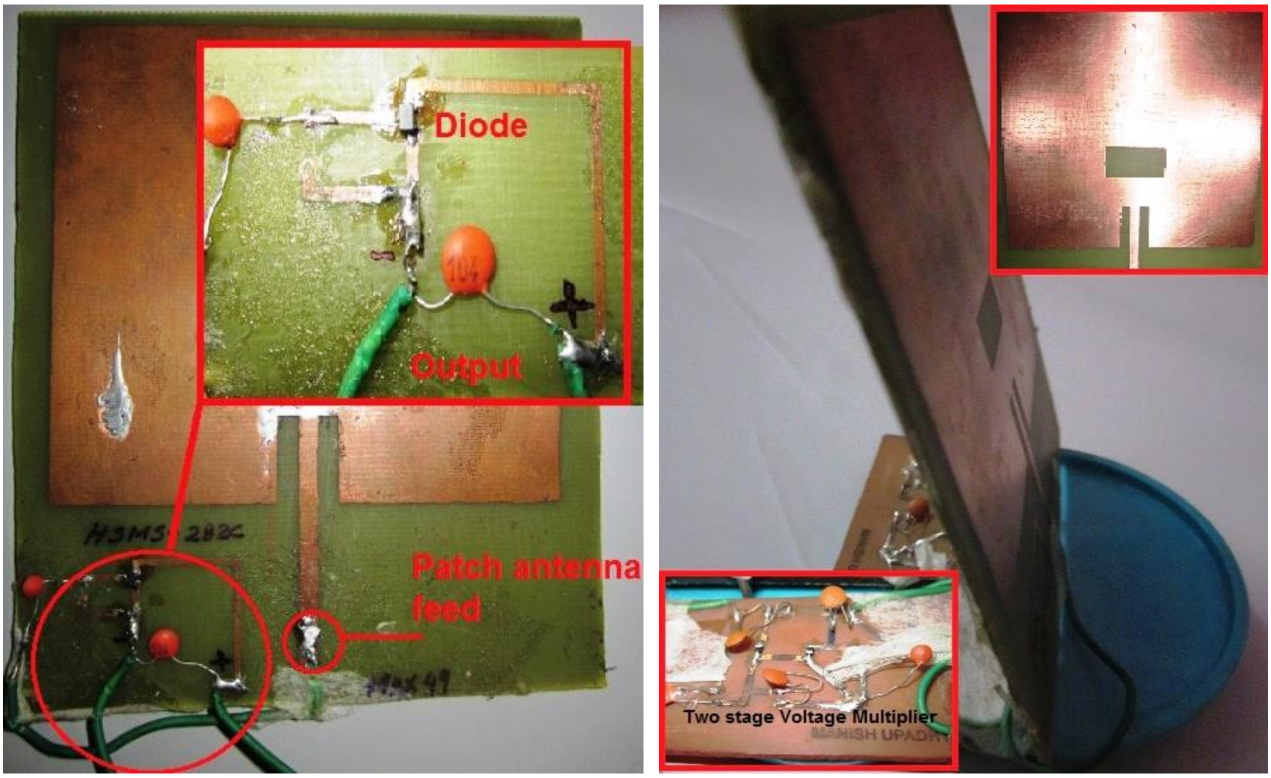
- Frequency of operation (fo) : 886 MHz
- Dielectric constant of the substrate (εr) : 4.4
- Height of dielectric substrate (h) : 1.6 mm.

The parameters obtained using the formulas for inset feed [11] are:

- Total width of the antenna (W) : 86 mm
- Total length of the antenna (L) : 75 mm
- Effective Dielectric Constant (εreff) : 3.9262

At higher frequencies such as 800 or 1900MHz the low values of inductors are difficult to construct especially at board level circuit design. But using the inductor along with capacitor at integrated circuit level design greatly improves the performance. Resonant frequency is also influenced by diode capacitance as it is related with reverse diode voltage and input voltage. [6][23]

In order to test single and double stage voltage multiplier output both are fabricated on a Copper clad sheet (FR4).the single stage detector is embedded with the patch antenna as in fig.7 a) while the two stage diode detector is attached with patch antenna on it back side can be seen in inset of fig.7 b).



a) b)

Figure 7: Fabricated patch antenna with a) single stage diode (HSMS-282c) detector b) two stage diode (BAT-16) detector (voltage multiplier).

Some effects were previously observed by many researchers is that the circuit yields the optimal efficiency at a particular load value, that is, the circuit's efficiency decreases dramatically if the load value is too low or too high. Since the energy harvesting circuit consists of diodes, which are nonlinear devices, the circuit itself exhibits nonlinearity. This implies that the impedance of the energy harvesting circuit varies with the amount of power received from the antenna. Since the maximum power transfer occurs when the circuit is matched with the antenna, the impedance matching is usually performed at the particular input power. [17]

The RF signals can be captured using Multiband antenna such as quad band are easily available in market and usually work at 900MHz/1800MHz/1900MHz/2.4GHz. These are of usually whip type, but small size such as printed, patch, spiral antennas are also testable. A tuning capacitor (C_{tune}) is used to capture the maximum power at required frequency range. Using only Clamp capacitor in antenna matching circuit we can tune the antenna at its resonant frequency. The tuning Capacitor (C_{tune}) can be verified by using the following formula to resonate with antenna inductance ($L_{antenna}$), where f is the frequency of operation.

$$2\pi f = \frac{1}{\sqrt{L_{antenna} \times C_{tune}}} \qquad 1.$$

f = Reasonant Frequency
C_{tune} = Tuning Capacitor
$L_{antenna}$ = Antenna Inductance

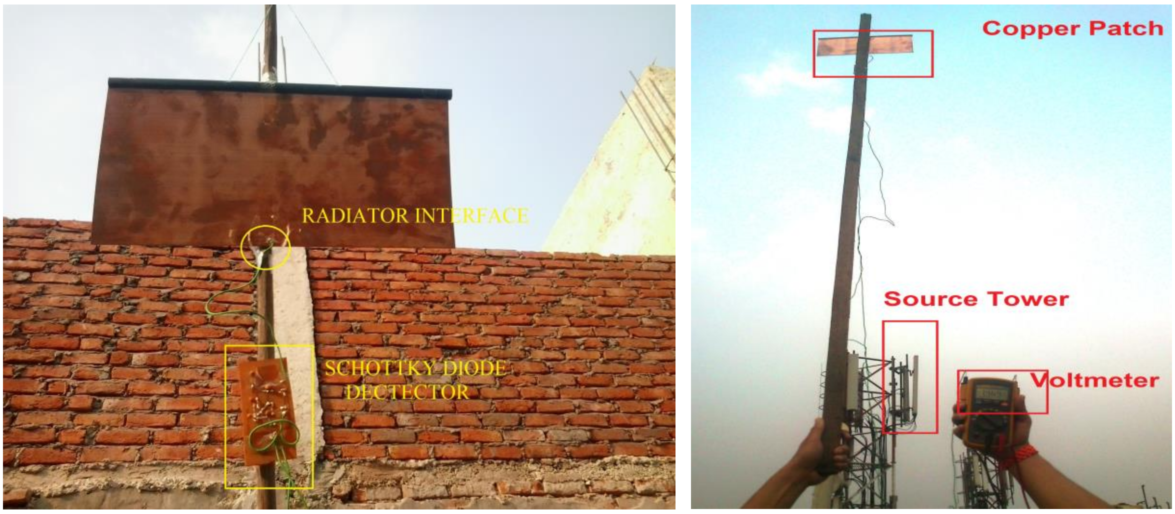
3. Test and Observation discussion

As per the block diagram representation the system required a (CDMA-GSM) RF source with known power level that is served by BTS tower near the lab. It is well known that in India the mobile tower have major band of operation in 877MHz-915MHz. For measurement it needs to determine the power at specified distance that is measured by Spectrum Analyzer and my four stages diode detector using 1N4148 is used earlier. Antenna for transmitting is assumed omni-directional whip antenna. While the antenna used in case of measurement of standard emission by RF source is measured using helical wire (unmatched) antenna on spectrum analyzer port and a copper patch for IN4148 diode detector.

Since the test receiver/detector used was a very low profile diode detector using 1N4148 (Semiconductor-semiconductor junction) which is having forward voltage drop ~620mV at 1mA and 1V at 15mA which is not an efficient value for the required application. For the final tests 1N4148 design is neglected and Schottkey Diodes (zero bias) like HSMS-282C AND BAT-16 that is designed for having very low forward voltage drop (approx. 340mV & 580mV respectively) and high switching speed is used.

3.1. Testing at external site

Setup shown in fig. 8 is a copper patch attached with two stage diode voltage multiplier to test electric field strength in vicinity of mobile phone tower. In order to make comparison of the electric field strength (V/m) near mobile phone tower antenna one needed to calculate ideal value of power that should be received and then the practical value measurement.



a) **b)**

Fig 8: Rectenna
a) using two stage schottkey diode detector b) Testing at external site (cell tower)

For calculation of ideal radiation figures/component certain parameters are assumed (on the basis of previous presented reports and data from Indian ministry of telecommunication site). These considerations could have deviation from standard one which may be the possible cause of difference reflected in practical measurement. Below present equation 2 to 7 are standard equations that are used with FRISS Model to calculate ideal values and to convert measured value. [17]

Parameters:

Frequency of interest (f) = 900 MHz (Between CDMA and GSM band)

Largest radiator dimension (D) = approx. 1 meter

Wavelength in meters (λ) = 0.33 meters

Typical Base station power (single carrier per operator) (Pt) = 10 watts/2 watt (amended Indian limit for radiation).

Typical Transmitter Antenna gain (Gt) = 17 dB

Receiver Antenna gain assumed to be (Gr) = -3.9 dB = -1.75 dBi (calculated with simulation model)

$$\mathrm{P_r} = Ae.\mathrm{E}.\mathrm{H} \quad 2.$$

$$Ae = g\frac{\lambda^2}{4\pi} \quad 3.$$

$$E = Z_o.\mathrm{H} \quad 4.$$

$$Z_o = 120\pi = 377\Omega \quad 5.$$

$$S = \frac{E^2}{Z_o} \quad 6.$$

$\mathrm{P_r}$ = Power received (W)
Ae = Antenna aperture (m)
E = Electric field strength (V/m)
H = Magnetic field strength (A/m)
λ = Wavelength (m)
g = Antenna gain
Z_O = Impedance (Ohm)
S = Power density (W/m2)

The **Fraunhofer** distance (d):

$$d = \frac{2.\mathrm{D}^2}{\lambda} = 6m \quad 7.$$

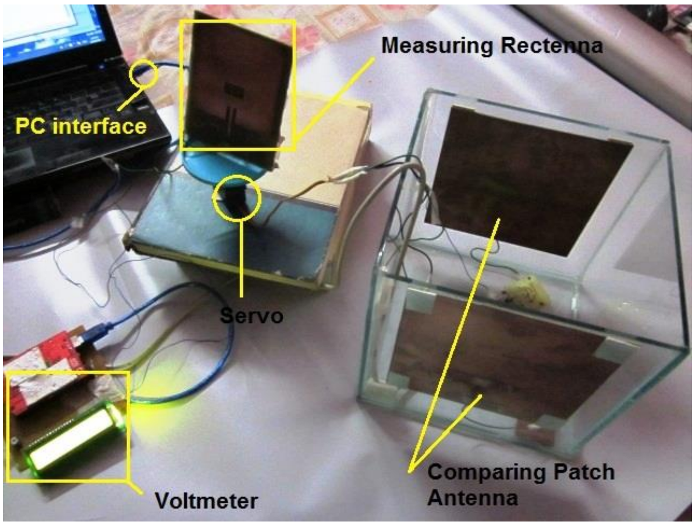
During measurement practice its is to be ensure that measurement is taken by maintaining minimum distance from cell tower because the Friss model of calculation that is to be used to estimate power received valid over far field only. The observations are presented in the table 1.Some quick conclusion that could be made is the test site reading are closer to ideal value one with the 2W/carrier standard.

Distance from Source	Power & Electric Field density (Ideal)			Power & Electric Field density strength Received (Test site)		
15 meter	177.3 mW/m^2	8.16 V/m	18.94 dBm	15 mW/m^2	2.44 V/m	-10.31 dBm
	35 mW/m^2	3.63 V/m	11.90 dBm			
30 meter	44 mW/m^2	4.07 V/m	12.89 dBm	6.7 mW/m^2	1.62 V/m	-13.97 dBm
	8.8 mW/m^2	1.82 V/m	5.90 dBm			
50 meter	15.9 mW/m^2	2.35 V/m	8.22 dBm	3.2 mW/m^2	1.1 V/m	-17.23 dBm
	3.1 mW/m^2	1.08 V/m	1.37 dBm			

Table 1: Test results comparison with ideal calculated values while mobile tower as RF source and two stage diode detector as receiver. Ideal transmitted power values correspond to RED = 10W/carrier & BLUE = 2W/carrier

3.2. Testing with the combined system

The combined system is presented in fig 9 a) which includes a glass container used to house two patch antennas connected with separate voltage multiplier which can be seen in fig 9 b) are connected to arduino uno (open source hardware platform with atmega-328) to its analog input pins. The measuring rectenna is mounted over a servo motor, which is controlled by the monitoring unit (microcontroller atmega-328).The voltmeter which is designed to measure electric field strength (V/m) is connected to the output of measuring antenna. The data to the analog pin of arduino uno is converted to equivalent digital bits and fed to laptop. The Matlab 2012a program on the laptop will collect data from arduino uno.



a)

When an RF source (CDMA-GSM band) like an operating cell phone with call initiated is brought near the measuring rectenna will result into an output voltage on voltmeter (field strength) as shown in fig 9. A program file written in the Matlab 2012a software which is for comparing output from the monitoring unit if executed, will start the arduino uno (monitoring unit); patch antenna on both the side of glass structure will start working to provide the strength of nearby field which will be input to the analog pins of arduino uno. Further the monitoring data will be fed to Matlab 2012a program executing on its way. The program will start plotting a real time graph of two voltages (for both the side of glass structure); on the basis of the relative strength of both antennas the program will command servo via arduino uno to move/target measuring rectenna toward the major RF source. In Fig. 9 c) the cell phone with a call initiated brought near the measuring rectenna, which result into an output of ~4.9V as pulsating DC is displayed on voltmeter LCD. Once the program is manually started in Matlab 2012a its activate both the patch antenna attached with monitoring unit as a result we can see the fig. 10 .The patch antennas are marked as right and left are assigned with color marker in Matlab 2012a graph plot. In Fig. 10 we can see that initially voltage plot is high due to the cell phone setting up communication with nearest tower. Another point we can notice is that the cell phone and the rectenna facing to the left side of the glass structure result into the left patch receiving most of the RF radiation.

Once we move RF source (cell phone) away from left side result into decreasing strength of RF radiation recorded by the blue line (left patch antenna) on the plot Eventually moving toward the right of the glass structure rise the RF strength recorded by right Patch antenna which will result into high red line strength on the plot. When the red line (right patch) record higher strength than a blue line (left patch),

The program will command servo to move measuring rectenna position (facing) from left to Right side .In this way, system will keep on comparing the strength and will automatically move measuring antenna toward more RF strength.

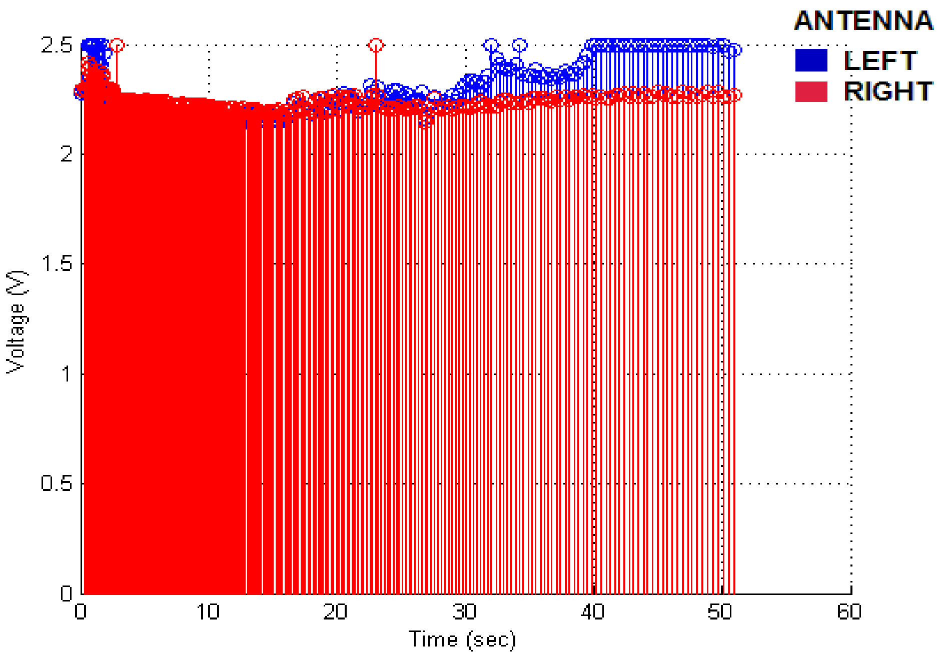

Figure 10: Plot for patch antenna on left (blue) and right (red) side of monitoring unit.

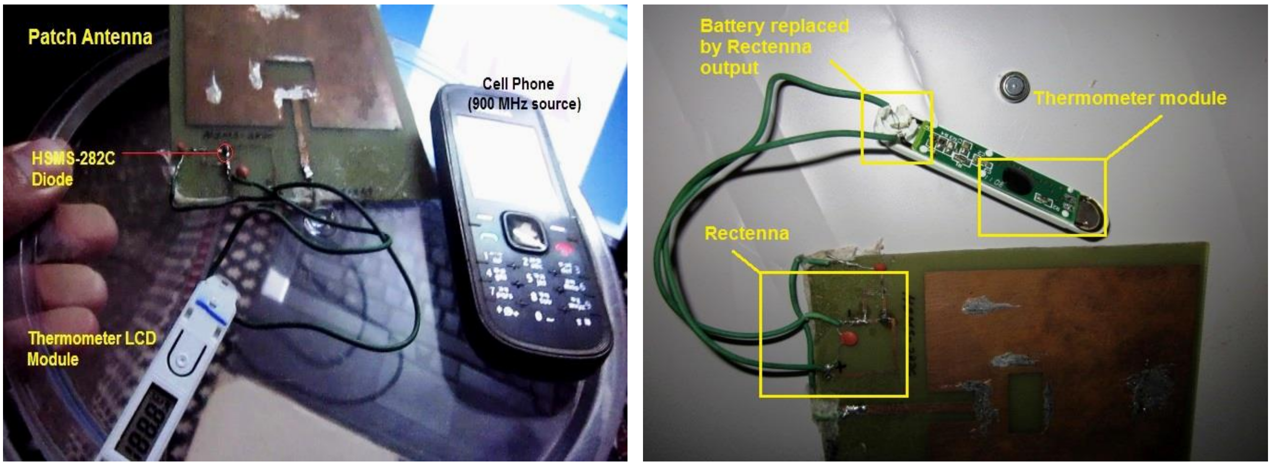
3.3. Powering LCD thermometer module

In fig 11 above presented a practice to power up an LCD thermometer module using the rectenna and a cell phone. As in fig 11 b) we can see that the battery from the thermometer module is replaced by rectenna output. Here in this case the wire connected to the battery section of the thermometer module is nothing but the output of single stage zero biased diode detector using (HSMS-282c), which will convert RF current to DC. When we brought a cell phone with an initiated call result in rectenna to provide dc voltage to the thermometer module as could be seen in fig. 11 a) the LCD on thermometer module start operating. Once the call terminated the rectenna stopped providing dc output result in the power to Thermometer module get down in very short span. Although the thermometer is able to operate for the very short span during an operating cell phone call still it is verified that power is enough to operate module but a consistent source of RF energy or a capacitor with low leakage and possibly with high discharge time.



a)

b)

Figure 11: LCD thermometer module a) powered by rectenna using cell phone as RF source, b) Battery is replaced by rectenna output.

4. Conclusion

A low profile RF (CDMA-GSM) energy measuring and harvesting system has been analyzed, designed and tested. The novel idea is to track/target the RF energy in real time to measure and harvest it. Voltage multiplier configurations, has been verified and optimized by means of test series conducted in lab and external site. Although no input low pass filter is used for rejection of harmonics at the input power of the rectifier still results gives good agreement to theoretical calculations.

A low profile inset-feed modified patch antenna is developed and used. A silicon based schottky diode single stage and 2 stage rectifiers are designed and fabricated on copper clad sheet (FR4). Comparison of ideal and RF energy measured with rectenna at test site with cell towers is presented.

Low series resistance Schottky diode in single stage detector is used to implement rectenna which could successfully power up the LCD thermometer. Although the power is not consistent for long use but system could be improved using super capacitor as output load of rectenna to operate low power devices.

Finally such system could be developed to be prove effective in charging of mobile handset (primary device) by placing to be charged mobile handset (secondary device) very close to fully charged mobile handset and draining primary device energy for charging the secondary device. Higher performance can be achieved by implemented the circuit in low sub micron manufacturing processes. Output voltage level can be increased using multiple stages of the multiplier circuit.

Chapter 1

Introduction:
Welcome to RF communications

As a trusted advisor for communications networks around the world, **CommScope** invests in people as much as our products and our industry. Our comprehensive training and education programs, participation in working groups on specs and standards, educational conferences, and extensive research are long-standing traditions that benefit everyone in our industry.

That's why we're pleased to present this book on the fundamentals of radio frequency (RF) communications for the wireless industry. We hope this valuable information will help foster a greater understanding of, and appreciation for, the technology, science and business behind modern RF communications.

The technologies and theories explored here are technical in nature, so we have made every effort to make the science of radio systems more accessible for a wider audience—whether you are an engineer or simply someone who works in this industry and wants to learn more about the basics of how RF communication works, including the issues involved in the planning, deployment and maintenance of communication networks.

Let's start by taking a look at the storied history behind the technologies that have shaped our on-the-go, wireless world.

RF systems, then and now

Wireless communications systems have been in commercial use since the 1940s. Some of the earliest implementations included community repeaters, paging systems, point-to-point links and specialized mobile radio (trunked) systems. More recent innovations and uses of the RF spectrum include cellular radio networks, which originated in the 1980s and now drive the cell phone and mobile device industry. Even more recent evolutions have given us familiar names like WiFi and WiMax, which let you connect to a network anywhere in your house, or virtually anywhere you go.

The shared link

This storied list of applications is incredibly diverse in purpose and design, yet every item shares at least one unique characteristic: they all utilize radio frequencies between 30 MHz and 2.6 GHz to move information between base locations and remote users.

The chain of components required to make this movement of information possible is a complex and varied one. As a proud supplier to the world's communications networks, **CommScope** is uniquely able to explore and explain these components, how they work, and more importantly, how they work together.

Doing our part

CommScope goes to great lengths to provide the best possible solution for every application. For simple or complex RF communications systems, each part chosen by an engineer must fulfill a specific role, determined by the expectations and limits placed on the installation itself. This book will explore several common components and how they interact, including:

- Antennas
- Coaxial cables
- Filters
- Duplexers and diplexers
- Amplifiers
- Remote radio heads
- Enclosures
- Power backups

... and many others

RF communications: the early years

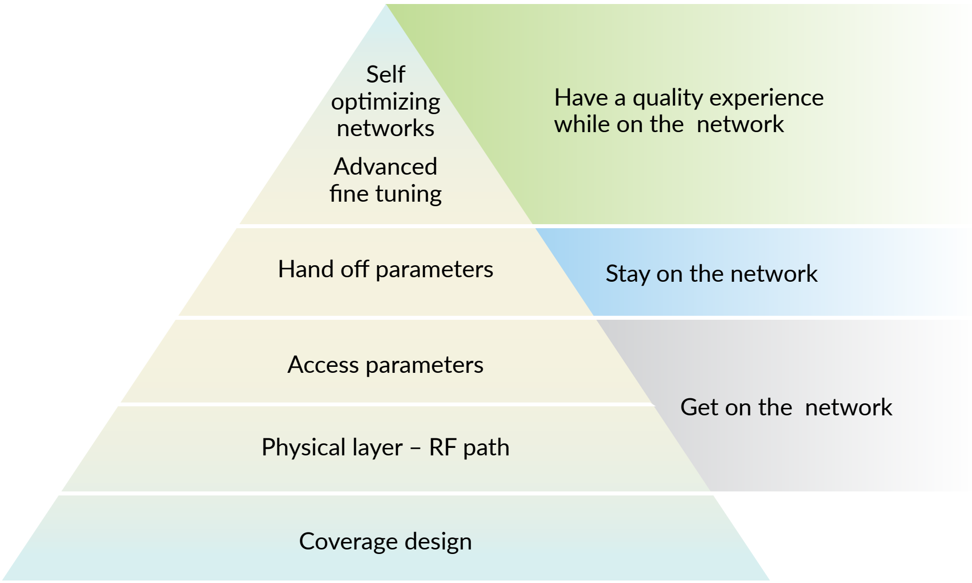
While the full story of RF communications is far from complete, the capabilities of modern RF technologies exceed the wildest dreams of the field's earliest pioneers. While we are all familiar with—and indeed, take for granted—living in a globally connected world, the early systems that laid the foundation for our networked existence were much less powerful.

The first RF systems featured a base radio using an omnidirectional antenna to communicate with one or more mobile users. Then, as now, the effective coverage radius of that base radio was limited by certain characteristics, such as RF power, antenna height, and the sensitivity of mobile receivers that were vulnerable to thermal noise and other interference sources. These systems were also limited by the fact that certain frequencies could only be used once in a particular geographical area. Once a mobile user left that area, no communication was possible.

The engineers of AT&T Bell Laboratories envisioned a future that would require much higher RF capacities to service thousands or millions of users at once. To deliver this future, they developed the cellular concept: a wireless network that uses lower antenna heights and transmission power levels to create limited-radius coverage areas that used and reused the same frequencies within its coverage area. Voice and data calls could be seamlessly handed off to neighboring cells as the user moved from one coverage area or cell to the next. The close-proximity reuse of radio channels is the fundamental concept of cellular telephones, and this is how today's wireless networks carry enormous traffic loads in spite of limited spectrum. The data riding these RF frequencies could be voice, data, or a combination of both; by intelligently managing and reusing the limited available bandwidth, the amount of available service increased by many orders of magnitude.

The business case for technical expertise

Cell providers monitor key performance indicators within their territories to identify coverage problems and assure customer satisfaction. These indicators include quality of service (QOS), dropped calls, failed access attempts, and other criteria. Their engineers are on the front lines of this battle for quality and constantly optimizing network performance as traffic grows. There are sophisticated parameters and advanced settings that help the RF engineer optimize a wireless network. However, successful wireless network optimization requires a solid foundation of physical components across the RF path (figure 1.1).



1.1: The interconnection of technology, design and optimization

The tuning and optimization of parameters can never be maximized without a high-performance RF path implemented with top-quality RF components. Conversely, wireless systems with weak RF paths perform poorly, resulting in expensive problems on both the operational and customer service fronts. Once a network is active, taking down a part of a cell network for maintenance is a costly and disruptive interruption; and, in most cases, one that could have been prevented by a better understanding of the site's requirements and the component choices available.

The path begins

Now that we understand the importance of foresight in planning, and insight in selection, we can begin this brief exploration of the many ways a modern RF communications network can come together. Thank you for joining **CommScope** on this journey.

Chapter 2

Where RF theory meets best practices:

Cell site development and construction

Building a new cell site raises some of the same questions as building a new house, such as deciding what materials to use, who to entrust with the construction, and how to get the best results for your money.

Of course, these problems are magnified when applied to cell site construction because there are so many different people, companies, municipalities and regulatory agencies involved. It takes a lot of experience to plan for every obstacle. That's why **CommScope** offers the following proven recommendations.

These general guidelines are the result of decades of successful, practical field work. While no guide can cover every aspect of cell site development, we'll cover the most commonly experienced technical issues here.

Service company
A cell site development partner responsible for actual construction on the site, including antenna towers, concrete footers and pads, security fencing, and equipment shelters.

You will work with several different companies and agencies in the process of developing your new cell site. You must be able to count on their competence and expertise. For each stage of development, you should become familiar with the challenges and requirements each partner will face. Knowing these factors will help you judge how well your partners are doing their work and the impact those factors will have on your network when the project is done.

Step one: choosing a service company

A ***service company*** will help you build the actual structure of your cell site. This includes the tower, shelters, cabinets, and other physical infrastructure to support the site's operation (figure 2.1). This can involve heavy, demanding construction work and the precision required by modern cell networks means a lot can go wrong at this stage.

2.1: A services company building a cell site tower

As with building any structure, it pays to research your construction company in advance. Here are some of the key facts you should learn before selecting your services company:

- **How long has the company been in business, and in the wireless field?** This is one of the first questions to ask. Experience matters as much as, if not more than, expertise.
- **How many employees do they have? How many of them work in the field and how many in their home offices?** Their staffing levels can directly affect how they handle your project.
- **How financially sound is the company?** For legal and logistical reasons, it's critical that they don't disappear in the middle of construction. Plus, they will need to maintain a certain minimum cash flow and credit to procure materials.
- **What are their expected payment terms?** Some require payment within 30 days. Others may allow as many as 90 days. Make sure their terms work with your cash flow, too.
- **What is their recent bond history?** For everyone's protection, all craftsmen in the field should be bonded. Looking at their bond history can give you a good picture of how well they perform.
- **What kind of insurance do they carry?** The company should offer to share their certificates of insurance. It's also smart to request a report on their recent claims history.
- **How does their safety plan hold up?** Unfortunately, some companies keep a generic plan on file simply as a token compliance effort. Speaking with the company's safety manager will tell you if they really understand the written plan.
- **What's in their OSHA logs?** The Occupational Safety and Health Administration (OSHA) monitors workplace safety; your potential services company should have a log of recent incidents, claims and actions. As a minimum, the previous three years should be reviewed for diligence and completeness.
- **Are their field employees properly certified?** All field employees should carry current certifications for first aid, CPR, the OSHA 10-hour training course, Competent Climber and Tower Rescue operations.
- **Is their gear properly certified for safety?** You should request copies of current climbing gear inspection certificates.
- **How is their workplace recordkeeping?** To see what you could expect for your project, ask to see their job site analysis worksheets.
- **What kind of vehicles will they be using?** If they use vehicles regulated by the Department of Transportation (DOT), request a copy of the DOT Carrier Safety Measurement System (CSMS) rating. Prior to 2011, this rating was called SafeStat, and some companies may still refer to it by that name.

In general, finding the answers to these questions is simply a matter of thorough due diligence. With so many certifications and other qualifications in play, you can see how important it is to know your services company partner as well as possible.

Coaxial cable
A type of cable featuring an inner conductive core, an outer conductive layer, and a dielectric, or insulating, space between them. Coaxial cable connects antennas to their base stations.

Step two: choosing coaxial cable and connectors

Efficient cell site operation relies on the precise pairing of components. As we will discuss in detail in chapter 3, certain cable types are designed to work with certain antennas. As we will explore in chapter 7, those cables must interface with their systems via connectors built for certain frequencies and power levels (figure 2.2).

An out-of-specification component or an improper installation of the correct component can cripple an entire system. For this reason, it's wise to contract with skilled engineers for the installation.

2.2: Coaxial cable examples; different types are available for different applications

Handling the cable and connectors during these installations is a delicate business. In general, observing these tips can help assure a trouble-free installation and dependable, long-term operation:

- **Use the right tool for the job.** Using the appropriate cable prep tool, usually available from the cable's manufacturer, is the only way to cut and prep cable ends for use in connections. Never use a saw; they leave metal filings behind, which cause poor electrical performance and problems with passive intermodulation (PIM).
- **Watch those tricky curves.** Different cable types have different degrees of allowable bend radii, or flexibility, so you must observe the manufacturer's prescribed bend radius for your particular cable. Bending too tightly can lead to poor electrical performance and failure in the RF path.
- **Keep your cables consistent.** If at all possible, use RF jumper cables from the same manufacturer to make those tight connections. Doing so provides consistent electrical performance and guarantees PIM performance.
- **Ensure proper cable support.** Manufacturers publish specifications describing how to support lengths of cable, both vertically and horizontally. Your specific guidelines will depend on your cable's construction, size and weight. If possible, use support clamps from the same manufacturer to avoid damage to the cable and loss of performance. Using third-party clamps may also invalidate your warranty.
- **Lift smart.** Getting cables up an antenna tower is difficult. Fortunately, using the correct hoisting grip will let you put that cable where it needs to be without damaging it. Hoisting grips come in several types and sizes, so make sure yours matches your cable's specifications.
- **Go to ground.** Grounding the cable is very important to prevent damage from lightning strikes. Best practices dictate at least three grounding points: at the top of the tower, at the bottom of the tower and just outside the entrance to the outbuilding, shelter or cabinet.
- **Put on the pressure.** Air dielectric cables use an air-filled gap to insulate the inner and outer conductors of a coaxial cable (chapter 7). This gap must be pressurized, like a bicycle tire, for the cable to hold its shape and prevent damage to the conductors inside. When installing air dielectric cable, it must be pressurized immediately. Leaving it overnight can lead to moisture condensation in the cable, which will degrade performance and is almost impossible to remove once introduced.
- **Finish with the seal of approval.** Connectors are particularly vulnerable to infiltration by weather and moisture. As soon as the connections are made, you should weatherproof them. Butyl tape is the preferred method, but in tight connection spaces, like those atop the antenna tower, you can opt for heat-shrink tubing applied with a heat gun.

By following these recommendations, you can help ensure that your cell site will operate at peak efficiency with minimal maintenance.

Electrical tilt antenna

An antenna fitted with actuators that can adjust its tilt relative to the ground. Changing tilt affects gain, or performance, of the antenna within defined geographical areas.

Step three: setting and troubleshooting remote electrical tilt antennas

Of the many ways you can improve performance from a cell site's antennas, a particularly effective method is beamtilt. It involves physically tilting the orientation of the antennas below the horizon, placing its greatest gain—its operational power—where it's needed most (chapter 3).

Efficiently changing the orientation of an antenna to realize this benefit is a matter of using electrical tilting mechanisms, or actuators, which can be operated from a remote location (figures 2.3, 2.4, and 2.5).

These mechanisms are controlled by an Antenna Interface Standards Group (AISG) Remote Electrical Tilt (RET) controller, which connects via AISG cables at the cell site for adjustment (figure 2.5).

2.3: An electrical tilt mechanism, or actuator, for a cell site antenna

2.4: A base station antenna (BSA) with integrated RET actuators

2.5: An example of an AISG RET controller module

As precision equipment, these tilting antennas can be a challenge to install and adjust properly. Getting the best result is a matter of understanding the software just as much as the hardware, but there are several ways to avoid common pitfalls:

- **Install the software first.** Before your crew goes to the cell site, install the manufacturer's software and become familiar with the controller's operation. This early training will help your team hit the ground running when they arrive.
- **Check for program updates.** Driver software for your electronic tilt actuator system is constantly updated to work with an ever-growing number of different antennas. Make sure your software is current by checking for updates on the manufacturer's website.
- **Understand the naming conventions.** To prevent onsite confusion, use conventions for the configuration of actuators that everyone will understand.
- **Test before installing.** For new installations, a little upfront effort can prevent big headaches later. Test the actuators, cables and other components before installing them on the tower. It's much easier to address problems when the components, and you, are on the ground.
- **Match antennas and tilts.** Not every antenna has the same tilt range, so be sure you select the correct one from the database before adjusting it. Each antenna's address is based on its product serial number, so be sure to keep a written record. You should double-check your tilts through tab reports generated by the controller.
- **Keep a spare cable on hand.** Bring a spare cable to the site in case you need to troubleshoot a non-reporting actuator. It's the fastest, surest way to tell if the problem is a faulty actuator or just a bad cable.
- **Check before tilting.** Before making any new tilt adjustments, pre-scan the other antennas to determine their tilt values.
- **Double-check your work.** After making the adjustment, you should perform a post-scan to confirm the new settings have been correctly applied.
- **Don't weatherproof cables and connectors.** Using electrical tape won't keep moisture out, in fact, it gives water a place to accumulate in the connector, where it can cause shorts.
- **Protect against lightning**. Lightning protection units should be installed at the base of the tower, or just before the cable enters the shelter or cabinet. Also, as stated above, it should be grounded in at least three locations: at the top of the tower, at the bottom of the tower, and just before entering the shelter or cabinet.
- **Don't splice in a ground lead.** Cutting into the jacket to attach a ground to the thin foil tape inside will cause water migration, damaging the conductors below the foil.
- **Go right to the source for cable.** It's considered good practice to purchase your cable directly from the manufacturer rather than obtaining it from a third party. Each manufacturer's system requires specific electrical conductors, and using a mismatched cable may lead to actuator failure, voiding your warranty.
- **Make the right connections.** The home run cable's male connector—the end with the pins—is the end that connects to the controller. Also, be careful not to cross-thread actuator cables at the controller or on the actuator itself. They should be hand-tightened only. Never use a wrench.
- **Cycle the actuators when you're done.** After addressing each actuator, cycle it fully to confirm there are no hidden problems.
- **Check for cable stress.** All cables should be free of stress and secured in intervals of 18 to 24 inches.

Thorough planning and clear procedures like these will ensure that your cell site reaches and maintains its maximum potential while also allowing you to make the proper adjustments as your network evolves.

Best practices always yield the best results

Like building a house, there are countless ways for things to go wrong when building a cell site—which makes it all the more important to work with a partner who has the expertise and experience you need to do the job right. **CommScope's** long history of expertise can turn your next project into your next success.

Chapter 2 summary

Cell site development and construction:

- Research and choose a reliable services company
- Know your cables and connectors
- Maximize gain with electrical tilt antennas

Getting the signal across:
Base station antennas

Today, the quest for a stronger signal strength—or for some, any signal strength at al—has become a routine part of our daily lives. We're always searching for a way to get more "bars" on our cell phones or faster Wi-Fi connections on our computers. Whether you're at home, at work or on the go, you need good reception to communicate and good reception depends on antennas.

The antenna is one of the most critical parts of both transmitters and receivers, and often, it's the most visible. You can see big antennas mounted on tall towers, and small ones attached to Wi-Fi adapters or cell phones. Antennas come in all shapes and sizes because each one is built for a specific purpose. However, all antennas share a common link: they are the key to how well and how far communications can be shared.

CommScope invests significant research and resources in the development of reliable, high-performance antennas, technology and innovation to better support evolving networks around the world.

Antenna
The portion of an RF system that radiates radio energy into space and collects it from space.

Dummy load
A simulated power load applied to an electrical system for testing purposes.

What is an antenna?

At its most basic level, an *antenna* is the portion of a radio system that can:

1. Take radio energy from a transmission line and radiate it into space in a predictable pattern, and
2. Receive radio energy from open space and feed it back down the transmission line.

Antennas are surprisingly efficient in this line-to-space and space-to-line energy conversion process. In fact, when properly configured with the right components, antennas can yield 80 percent efficiency or greater—a remarkably high figure in engineering terms. By way of comparison, consider the common incandescent light bulb, which yields only 20 percent efficiency. This means that, of the amount of energy put into a bulb as electricity, only 20 percent of that energy is put out as light. An important consideration to maintain an antenna's extraordinary efficiency lies in the transmission cable that connects it to the transmitter.

Matching the line

To get maximum efficiency from a radio transmission's power, the antenna and cable must share certain characteristics to avoid wasted energy. For example, if a radio system uses an industry standard coaxial cable fixed at 50 ohms to connect the antenna and its transmitter, the antenna itself must rate reasonably close to 50 ohms as well.

Testing this configuration is a simple task. We connect the coaxial cable to the transmitter and place a 50-ohm *"dummy load"* on the other end to simulate an antenna. Using a watt meter will reveal two important factors that measure the efficiency of the system:

1. The amount of power entering the cable from the transmitter, and
2. The amount of power reaching the dummy load.

The difference between these two measurements represents the power lost in the line itself. The better matched the cable, the smaller the difference, and the more power reaches our simulated antenna.

If we reduce the simulated antenna's load from 50 ohms to just 25 ohms, 11 percent of the energy sent through the coaxial cable would be uselessly returned to the transmitter. That would yield very low efficiency unless we were to replace the 50-ohm coaxial cable with one rated at near 25 ohms, thereby restoring the balance. However, the 25 ohm cable would move mismatch to the source end where it connects to the transmitter.

Like water pouring through a funnel, the amount of throughput is dictated by the tightest portion of the route. In a radio system, the excess energy bounces between the transmitter and the antenna, which must reject all power above its capacity. This endlessly reflected power creates a measurable wave pattern in the cable, an effect called the voltage standing wave ratio (VSWR).

VSWR is the measurement of how well-matched a transmission line is to its antenna. Expressed as a ratio, a VSWR of 1.0:1 indicates a perfect match. Likewise, a VSWR of 1.5:1 indicates a 4 percent power reflection, which is another way of describing 96 percent efficiency, where 96 percent of the power output from the transmitter actually makes it to the antenna (table 3.1).

Voltage standing wave ratio (VSWR)
A measurement of the power reflected between transmitter and antenna in a transmission line that connects the two. This figure yields the system's transmission efficiency.

Calculating voltage standing wave ratio (VSWR)

VSWR	Return loss (dB)	Reflected power (%)	Through power (%)
1.10	26.5	0.2	99.8
1.25	19.1	1.2	98.8
1.50	14.1	4.0	96.0
1.75	11.6	7.4	92.6
2.00	10.0	11.0	89.0

VSWR = $[1 + 10^{((-\text{Return Loss})/20)}]/[1 - 10^{((-\text{Return Loss})/20)}]$

3.1: Calculating VSWR, and some sample efficiencies

Velocity, frequency and wavelength

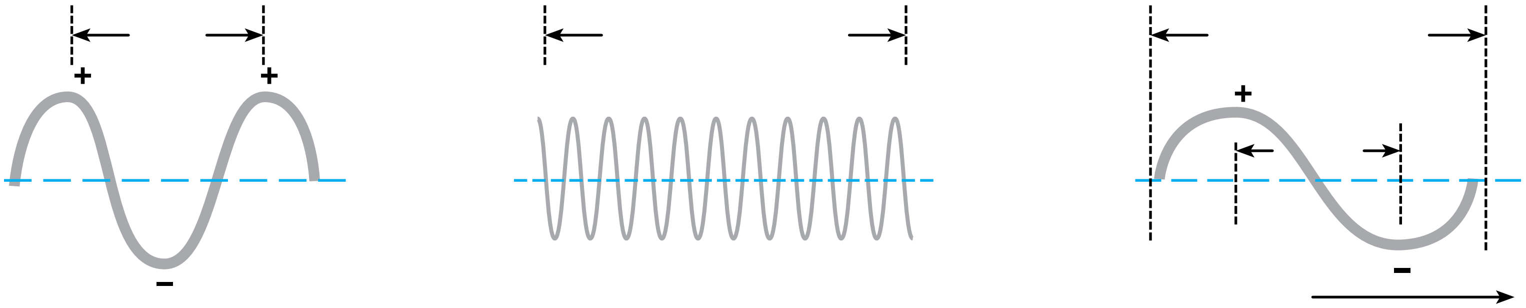
Like all forms of radiation, including visible light, radio waves travel about 186,000 miles, or nearly a billion feet, per second. Like other forms of radiation, radio waves oscillate, or flip back and forth, between plus and minus at a predictable rate. Each complete flip is called a cycle, and cycles are expressed in hertz (figure 3.2). Measuring how many cycles, or hertz, a signal oscillates per second gives us its frequency—literally, how "frequently" the signal oscillates in one second.

Knowing a signal's speed and its frequency, we can divide the first by the second to determine its wavelength—the distance the signal travels while completing one full cycle. Wavelengths are usually measured in feet or inches, and are useful in understanding what it means to be "in phase" or "out of phase," which we'll explore later in this chapter.

Antennas are two-way streets

In theory, antennas transmit and receive in precisely the same way; the same processes occur both ways. Only the direction is reversed. In actual practice, however, a number of complicating factors, particularly on the receiving end, can impact the efficiency with which the antenna operates.

To demonstrate, it is perhaps easiest to explore the most basic of antennas: the half-wave dipole.



A cycle completes itself traveling from plus to minus back to plus.

The number of cycles in one second gives the frequency.

The speed divided by the frequency gives the distance the wave travels in one cycle. This is called the wavelength.

3.2: Relationship of time, frequency, and wavelength

Half-wave dipole

The half-wave dipole radiator antenna, often just called a "dipole," is the most basic one used in two-way base station applications. It is essentially nothing more than a straight conductor made of wire, rod or tubing that measures exactly half of its assigned frequency's wavelength. A rule of thumb for determining the correct length is:

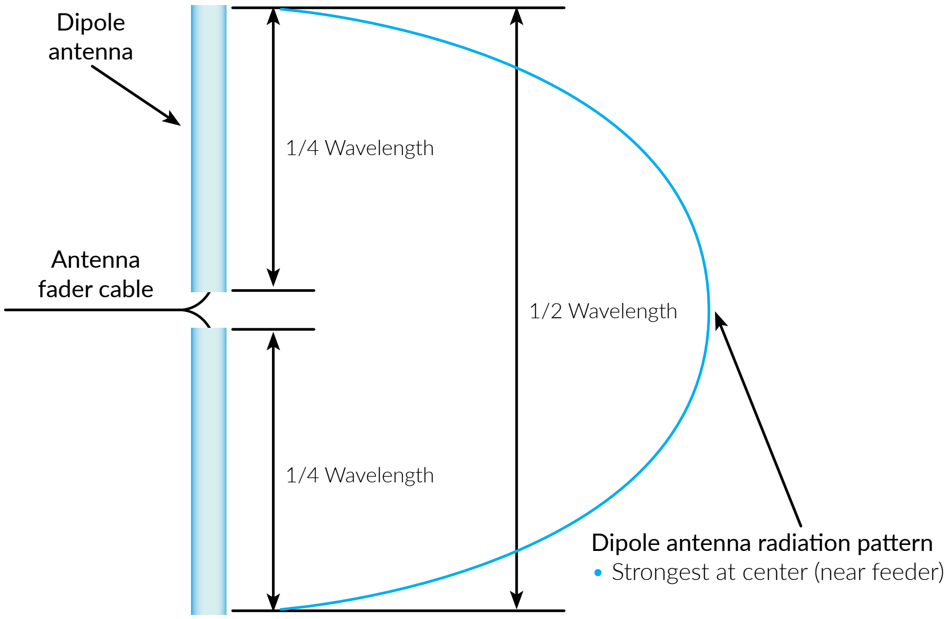
Length (in inches) = 492 divided by the desired frequency in MHz

As a result, dipole antenna length can be highly variable. It could be just 2.4 inches in length for a frequency of 2500 MHz, or 20 feet long for a frequency of 25 MHz. The table below provides more examples (table 3.3).

Generally, the feeder line is connected at the midpoint, so the antenna radiates at maximum intensity in the middle of the dipole. (figure 3.4).

Frequency (MHz)	1/2 Wavelength (inches)	Frequency (MHz)	1/2 Wavelength (inches)
30	196.8	800	7.4
50	118.1	900	6.6
74	79.8	1700	3.5
150	39.4	1900	3.1
220	26.8	2100	2.8
450	13.1	2500	2.4
750	7.9	3500	1.7

3.3: Half wavelengths of two-way frequencies



Dipole antenna
1/4 Wavelength
Antenna fader cable
1/2 Wavelength
1/4 Wavelength
Dipole antenna radiation pattern
• Strongest at center (near feeder)

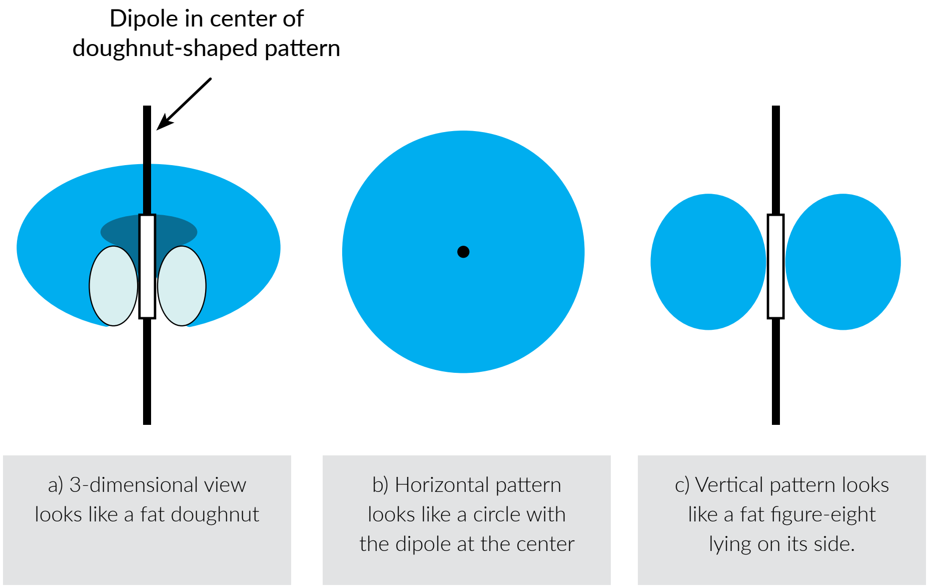
3.4: Dipole antenna construction and radiation pattern

Vertical and horizontal antenna radiation patterns

All antennas, regardless of polarization, have three-dimensional radiation patterns. If the pattern is extended in all directions equally, the resulting shape would be a sphere, with the antenna at its center. The polarization of the antenna determines which portion of that sphere represents an antenna's actual pattern. Slicing the sphere vertically yields a vertical circle while a horizontal slice would reveal a horizontal circle.

These theoretical descriptions of the two polarization patterns appear to be omnidirectional within their planes, but that's not quite the case. In practice, there are no truly omnidirectional antennas. Our example, half-wave dipole antenna, for instance, reveals the truth (figure 3.5). The pattern appears circular, like a doughnut, on a horizontal plane, but forms a figure-8 in the vertical plane.

As we will see later in this section, most real-world antennas consist of a vertical array of radiating elements and elevation pattern shaping has become quite important for interference minimization (figure 3.18).



Dipole in center of
doughnut-shaped pattern

a) 3-dimensional view looks like a fat doughnut

b) Horizontal pattern looks like a circle with the dipole at the center

c) Vertical pattern looks like a fat figure-eight lying on its side.

3.5: Radiation patterns for a dipole antenna

Antenna gain

Using our half-wave dipole as our reference, we measure gain in decibels (dB). Decibels are used to compare one quantity of power to another. So, taking our dipole as our starting point, we say it has a gain of one, or that it has a value of 0 dB, as it has “zero difference” from itself. If we have an antenna with double the power of our reference dipole, we find that its power ratio of 2.00 yields 3 dB in gain (table 3.6).

Power ratio	dB	Power ratio	dB
0.10	–10	1.00	0
0.13	– 9	1.26	1
0.16	– 8	1.58	2
0.20	– 7	2.00	3
0.25	– 6	2.50	4
0.32	– 5	3.16	5
0.40	– 4	4.00	6
0.50	– 3	5.00	7
0.63	– 2	6.30	8
0.79	– 1	8.00	9
1.00	– 0	10.00	10

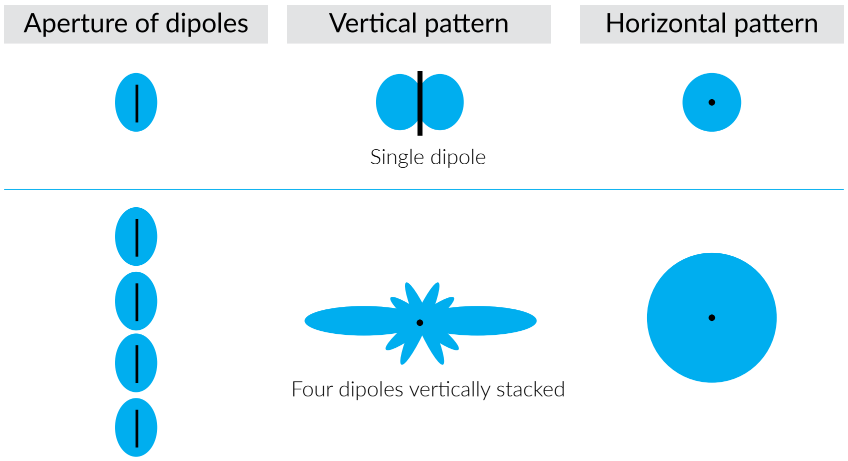
3.6: Deriving gain in dB from power ratios

Boosting gain

Theoretically, there are two ways to increase antenna gain.

1. We can increase the power or current density in the antenna so it will radiate its pattern with greater intensity. But as we discovered earlier, we cannot raise the power without fundamentally altering the mechanics of the antenna, cable and transmitter.
2. Alternately, we can change the radiation pattern, tightening its focus, so more of the existing power is directed where it will be used. This can be done without changing out hardware.

Consider again the circular, doughnut-shape pattern of our dipole antenna (figure 3.7). By “squashing” the doughnut vertically, we produce a denser, flatter, rounder pattern. As a consequence, the circle also grows larger as vertical space is traded for horizontal space. Since verticality is rarely of importance, this is a very profitable exchange.



3.7: This figure illustrates how stacking four dipoles vertically in line changes the pattern shape (squashes the doughnut and increases the gain over a single dipole). The area of the horizontal pattern measures the gain. The small lobes in the lower center section are secondary minor lobes.

In phase
Multiple antennas radiating together at precisely the same time and rate.

Omnidirectional pattern gain antennas

To achieve greater gain in this circular (or omnidirectional) pattern, we can stack multiple vertical dipole antennas above each other, as shown in figure 3.7. This increases the vertical size of the antenna. Then, we feed power to the dipoles in such a way that they add together at a distant point—again, with transmission lines matching their radiation power limits for greatest efficiency. By feeding equal amounts of power that arrive at each dipole at the same instant, the dipoles radiate ***"in phase,"*** or in synchronicity, for improved gain by virtue of its pattern.

This type of antenna is called a vertical collinear phased array, and it is the most commonly used type of base station antenna.

Aperture

Aperture, or beam width, determines the gain of an antenna. Like an adjustable nozzle on a garden hose, aperture describes the degree to which the signal is focused: the tighter the focus, the greater the gain within that area of focus.

Spacing of dipole elements

In a vertical collinear array, each dipole or sub-array of dipoles is connected in parallel to the common feed point by a separate transmission line. This means it's possible to locate the dipoles so that their vertical separation tightens overall aperture to boost gain. This separation is usually something less than a single wavelength of the assigned frequency being transmitted. Anything less tends to reduce the improvements in gain.

Feeding the array

In a vertical collinear array of two or more dipoles, the most common means of feeding power via the coaxial transmission lines are:

> **Parallel (shunt) feed.** Power is fed along individual lines to each dipole or sub-array of dipoles. Using matching transformers and junctions, the cables connect to the line running down the tower. This allows the array to be fed from the center, equalizing the effectiveness of each array element and preventing the beam tilt that affects series-fed installations.

In either application, the physical length of the aperture directly determines the amount of gain.

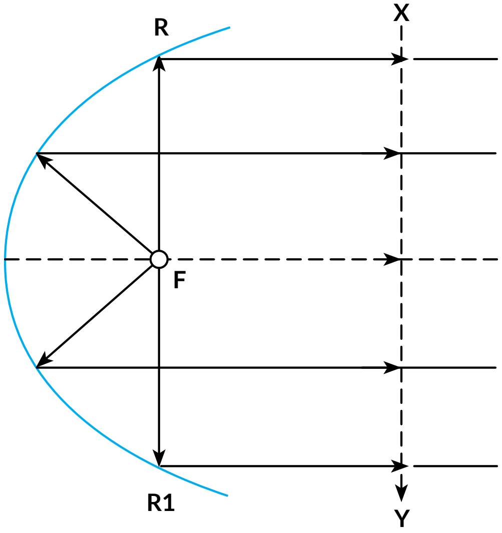
Directional gain antennas

While omnidirectional gain antennas like the vertical collinear array achieve greater gain by compressing its vertical pattern into a flatter circular shape, there are other types of antenna that modify their horizontal patterns to accomplish the same gain improvements.

Dipole and reflector

As we've shown, a vertical dipole antenna has a circular horizontal pattern. However, if we position it in front of a metal screen or wire mesh, we see that radiation going to the rear will be blocked (figure 3.8). If this blocked radiation is reflected off this screen, the horizontal pattern will no longer be circular, but directional.

If a dipole is positioned exactly one-quarter wavelength from this reflection screen, the radiation that would ordinarily go to the rear is redirected to the front to form what is called a directional lobe. It's the same effect as that of the reflective mirror behind a flashlight's light bulb, which redirects the circular light pattern into a single direction. The larger the screen, the greater the reflection and the narrower the directional lobe becomes—and just as the omnidirectional antenna increases gain by compressing vertically, this directional antenna increases gain by compressing horizontally and directing all its power in a single direction.

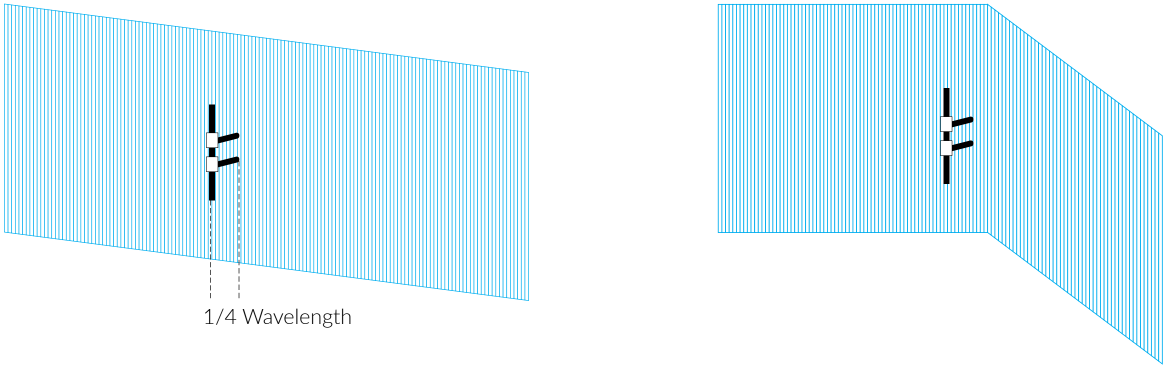


3.8: The omnidirectional pattern of a dipole can be made directional

Corner reflector and parabolic reflector

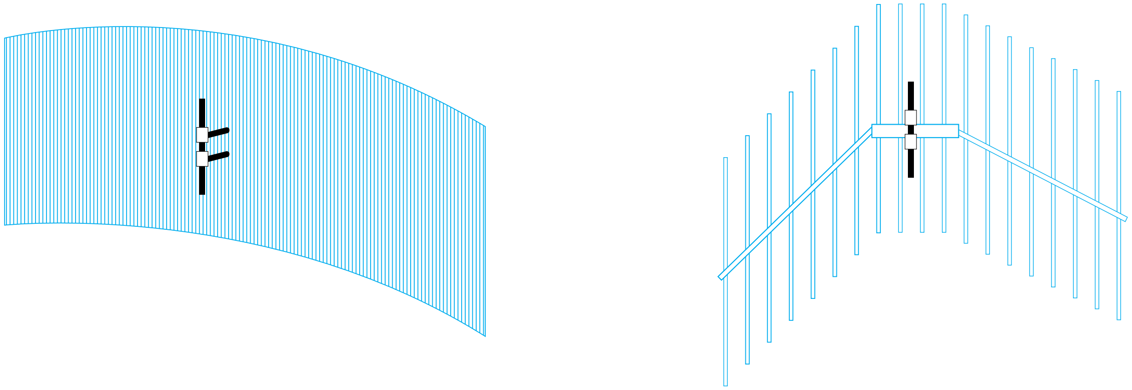
Corner reflectors are right-angled V shapes, with their vertices spaced a certain distance from the dipole (figure 3.9). The resulting reduced beam width and the corresponding increased gain is determined by the size, shape and distance of the screen from the dipole.

Modifying this corner reflector into a rounded bowl shape creates a parabolic reflector, with the dipole placed at its focal point. In either application, the reflector may be built of closely spaced rods instead of wire mesh, increasing the strength and reducing the wind drag of the reflector.



Flat screen
Radiation to the rear is blocked

Corner screen
The screen behind the dipole cuts off radiation to the back and reflects it forward to form a beam



Parabolic screen
The parabolic screen focuses on the beam

Corner reflector
Vertical rods replace the scree of the corner screen to make a reflector of stronger mechanical design

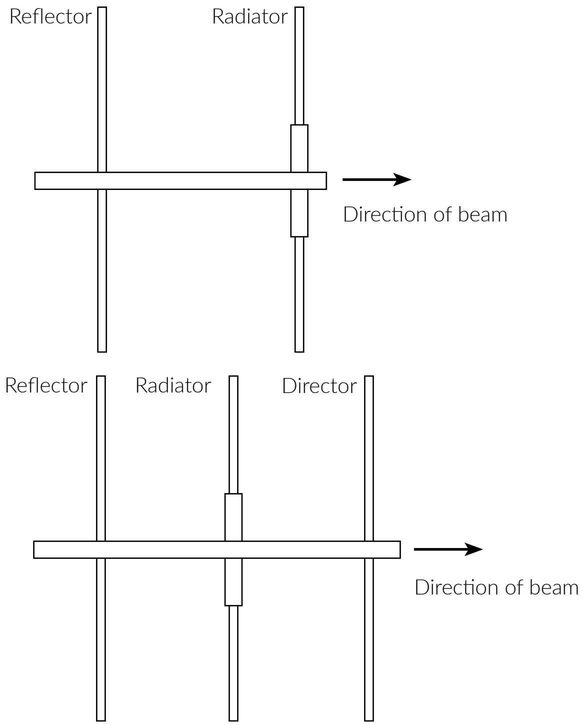
3.9: Dipole antenna reflector shapes

The Yagi antenna

Perhaps the most commonly used directional antenna is the Yagi antenna. The Yagi offers many variations and forms, but it generally consists of three elements (figure 3.10):

1. Radiator
2. Reflector
3. Director

These components are arranged such that the director is in the front, the radiator behind that, and the reflector behind both. Generally, the director is the shortest component, and the reflector the longest. The spatial relationships between the three elements determine the power that goes into the Yagi's directional lobe, and therefore also determine the Yagi's gain. It is an efficient and flexible design, offering high gain, low weight, minimal wind drag and modest cost, resulting in its popularity for two-way radio communications.



3.10: Two-element and three-element Yagi directional antenna

Yagi antenna
Also known as an Yagi-Uda antenna, this is a common type of directional antenna, first created in Japan in 1926 by Hidetsugu Yagi and Shintaro Uda.

The bandwidth factor

Another consideration in antenna construction is that of bandwidth. As we discussed in our description of the dipole, antennas must be built to lengths that are determined by their operating frequency wavelengths. As you may recall, the dipole antenna must be half the length of its assigned wavelength. However, it is possible to build an antenna that covers a range of frequency bands or bandwidth centered around a particular frequency.

Indeed, nearly every antenna in use today affords a fairly wide percentage of bandwidth. In fact, certain antenna designs in the 1900 MHz frequency range can offer over 45 percent bandwidth (1710-2690 MHz). These are known as ultra-wideband antennas.

The bottom line of antenna design

We've just covered the basics of antenna design, but it's important to keep in mind that there are no magic formulas or one "ideal" antenna configuration. Improving one aspect of operation always comes at the expense of another aspect. The best design is always one that is driven by the specific operational objectives of the antenna.

Cellular antenna concepts

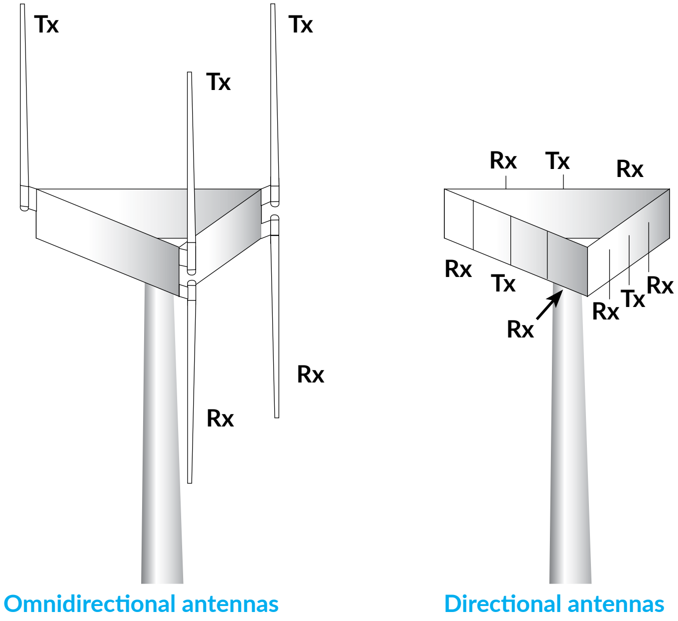
Now that you have a basic working knowledge of antennas and how specific configurations can help them perform even better—that is, by improving gain. Let's look at a much more specialized and sophisticated category: the cellular antenna.

Cellular antennas are a familiar feature in nearly every corner of the world. In many cases, these are cellular networks that bring new connectivity where it had never before been possible, and these connections depend on cellular base station antennas.

In cellular base stations, there are two basic antenna types currently in use (figure 3.11):

1. **Omnidirectional antennas,** which we defined previously as antennas that exhibit a circular radiation pattern and operate in virtually all directions, and
2. **Directional (or sector) antennas,** which operate in a specific direction, most commonly covering an arc of 120 degrees or less, depending on capacity requirements.

Figure 3.11 shows older legacy sites using vertically polarized antennas. Rural sites typically used 90° horizontal beamwidth models, suburban sites used 65° models and urban sites used models ranging from 33° to 65°. In these cases, two Rx antennas were required per sector to support Rx diversity. For modern sites, a single Dual-pol (±45° polarization) model with the appropriate horizontal beamwidth supports Rx diversity.



3.11: The two types of commonly-used cellular base station antennas

Cell reuse

What makes cellular networks different from other types of communications is the principle of cell reuse. Cell reuse is a way of increasing network capacity by “reusing,” or reassigning, individual frequencies on the fly within a particular cell.

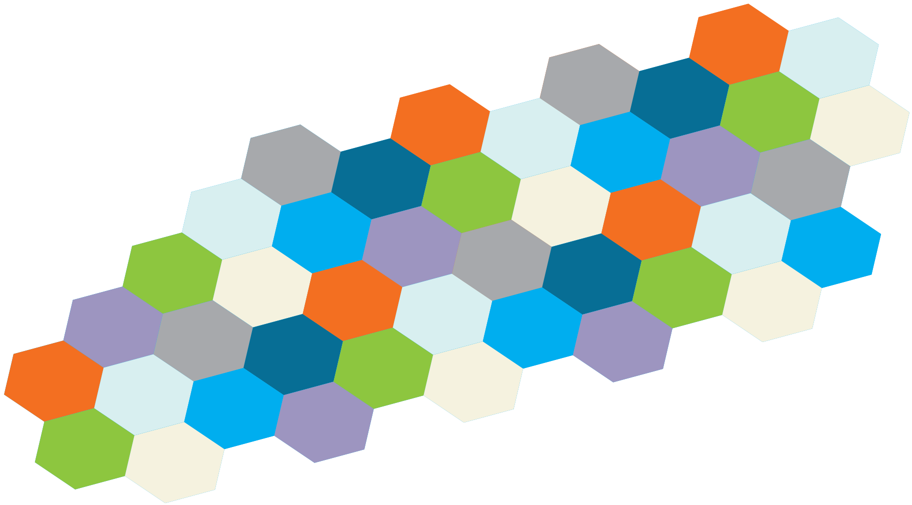
To see this process in action, consider the shape of cells and how they fit together. Typically, cells are represented as interlocking hexagons, as seen below (figure 3.12). Depending on the density of the area served, these hexagons can be miles across or cover just a few hundred feet.

As a result of this incredible flexibility, channel sensitivity is limited by external interference rather than noise issues, as older radio communications have traditionally been. The specialized pattern shaping available with directional antennas, both in azimuth (horizontal direction) and elevation (vertical space), allows incredibly precise coverage that doesn’t interfere with neighboring cells.

Antenna characteristics

A cellular base station’s antenna is the most critical consideration in an efficient cellular network, and it all depends on choosing the antenna with exactly the right physical characteristics for a specific application. These characteristics relate to radiation pattern, antenna gain, front-to-back ratio and a number of other critical factors.

In the real world, defining, choosing and testing these characteristics requires a great deal of technical expertise and mathematical skill, so for the purposes of this discussion, we will cover the basics with a far more generalized approach than an engineer would use in an actual evaluation.



3.12: Cell reuse in a sample map. The entire map can be covered with just 7 unique cells and still provide adequate channel isolation between cells.

Radiation pattern
The three-dimensional shape of an antenna's strongest signal transmission.

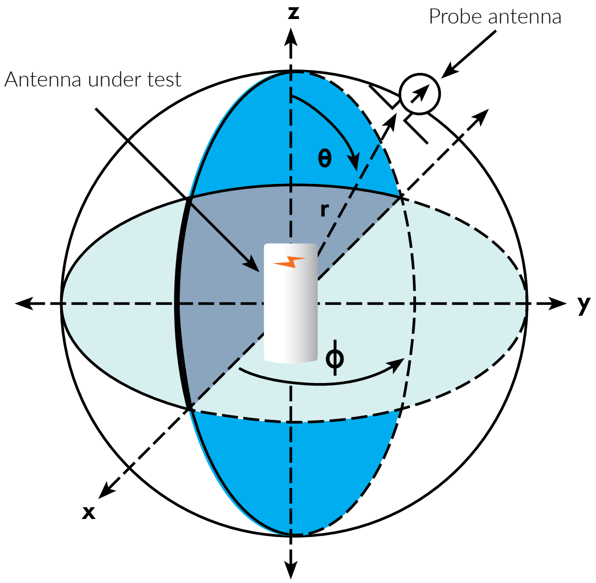
Spherical coordinate system
A geometric polar coordinate system used to mathematically map the radiation pattern of antennas.

Azimuth coordinate system
The polar coordinate system used in the field by RF engineers and surveyors to map the radiation pattern of antennas.

Radiation pattern

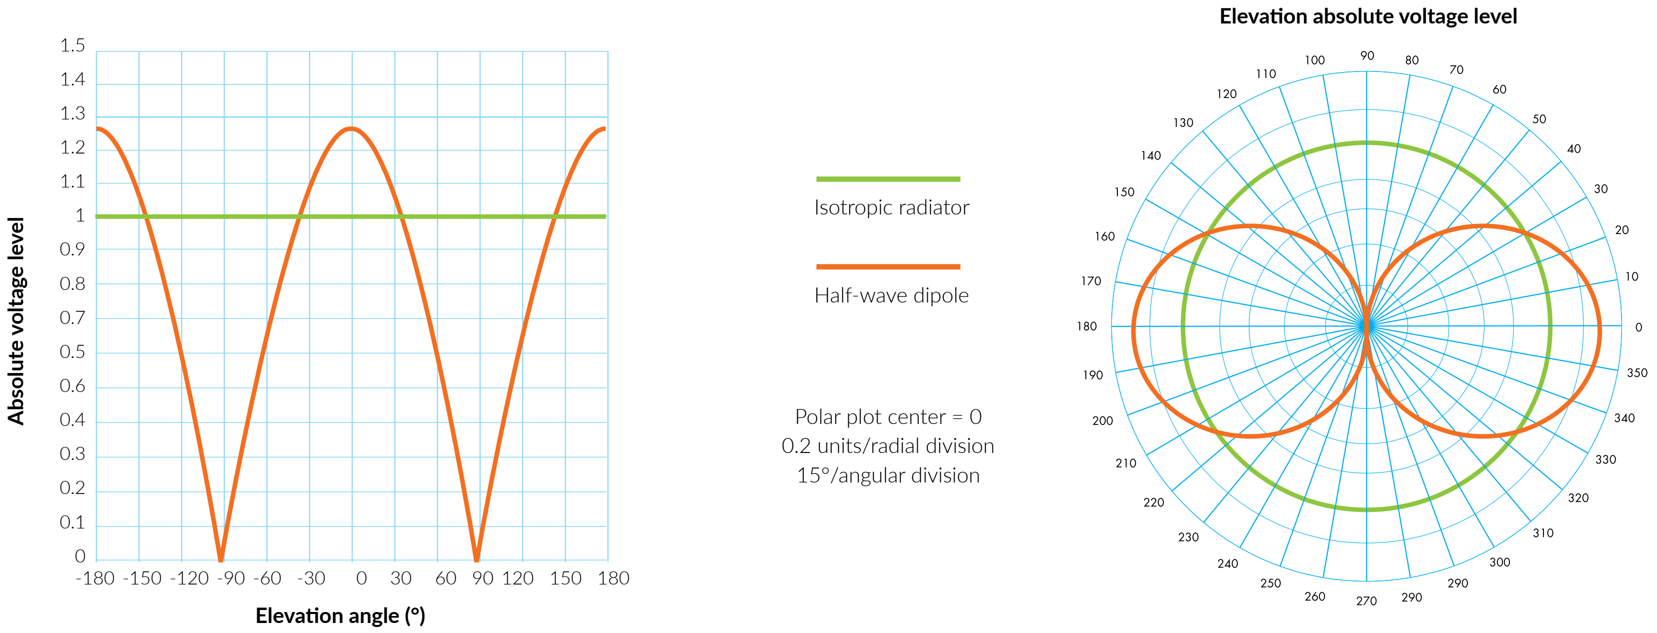
Perhaps the most obvious and important characteristic to understand is an antenna's radiation pattern. If a particular application calls for coverage in all directions, you would choose an antenna with a circular or omnidirectional radiation pattern. If your installation requires a more focused signal, a directional antenna's radiation pattern would satisfy your needs.

Mapping an antenna's radiation pattern is a fairly simple task. Connecting a probe antenna to a receiver and moving it around your tested antenna at a fixed distance allows you see the variations in signal strength. Mapping these readings with polar coordinates yields a three-dimensional map showing in which directions the antenna transmits most strongly (figure 3.13).



3.13: Moving a probe antenna around the tested antenna at a fixed distance yields a three-dimensional map of its radiation pattern

At the same time, a pattern can also be expressed as a conventional rectangular plot with angular position on the X-axis and signal strength on the Y-axis. Examples of both are shown below. Depending on the design of the antenna, the radiation pattern can display any number of shapes. The isotropic dBi reference is a theoretical "point source" and thus generates a pattern covering all directions of a sphere. As seen previously, the ½ wave dipole dBd reference pattern has nulls above and below the dipole and thus from a conservation of energy standpoint must have more gain on the horizon than the dBi reference. The absolute difference of these two standards is 2.14 dB and today most manufacturers rate their products in both dBi and dBd. Since an antenna's gain is determined by comparing it to one of these standards, the dBi rating will always be 2.14 dB greater than the dBd rating.



3.14: A system controller interface displaying voltage, amperage and alerts

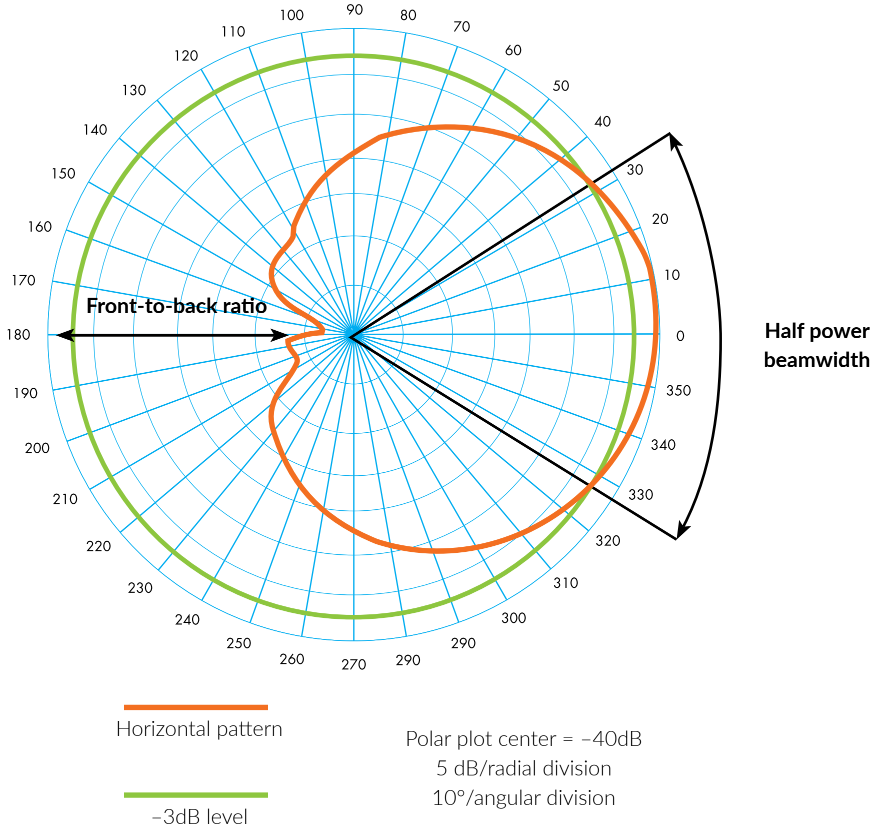
Antenna gain

As discussed earlier, an antenna’s radiation pattern is directly connected to its gain, or performance power. While we cannot improve gain by increasing transmitter power without rebuilding the system entirely, we can use radiation patterns to achieve the same objective.

Gain is measured in decibels (dB) and rises as a function of increasing aperture size, which in most cases means increasing the physical size of the antenna. As a general rule, a doubling of aperture results in a doubling of gain. Though, as a practical matter, larger antennas introduce efficiency-reducing power losses that can diminish these improvements.

Front-to-back ratio

The ratio of a directional antenna’s maximum directivity to “front” (where its main lobe appears) to its “back” where its reflector is located is called, appropriately, the antenna’s front-to-back ratio (figure 3.17).

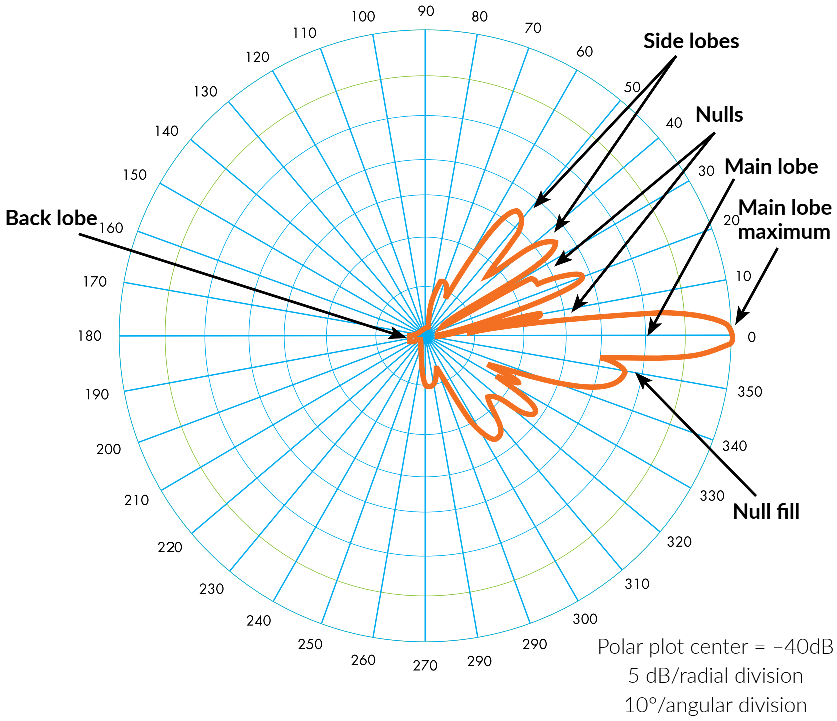


3.17: A polar representation of a directional antenna’s front-to-back ratio

Side lobes and nulls

Apart from a radiation pattern's main lobe, there can also exist side lobes and nulls. Side lobes are extraneous areas of strong signal, and nulls are the low-energy spaces between them (figure 3.18). Nulls may exhibit 30 dB or more of attenuation, meaning signals found there can be as weak as one one-thousandth of the power of the main lobe.

There are ways of redirecting side lobe power back into the main lobe. This process, called null fill, can result in the widening of the main lobe and reduce gain accordingly.



Polar plot center = –40dB
5 dB/radial division
10°/angular division

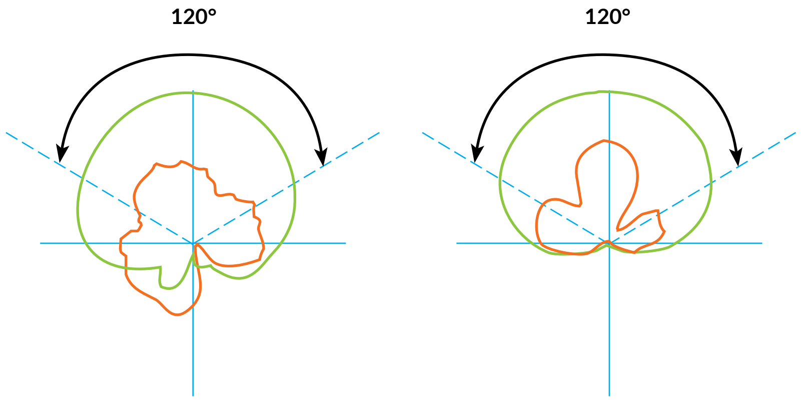
3.18: *A polar representation of a vertical pattern including side lobes and nulls*

Polarization

Polarization is a property of the wave produced by an antenna that describes the way that wave varies in space over time. In simpler terms, it describes the orientation of that wave, such as vertical or horizontal or slant 45 degrees (Dual-pol).

Cross-polarization ratio

This characteristic measures the performance of a dual-polarized array in distinguishing between orthogonal waves (two signals broadcast perpendicular to one another, such as horizontally and vertically). This figure is calculated as the ratio of co-polarization to cross-polarization occurring in the antenna's main lobe (figure 3.19).



3.19: Typical and directed dipole cross-polarization ratios

Sector power ratio

Basically, sector power ratio is a comparison of signal power registered outside and inside a desired receiving area as a consequence of an antenna's radiation pattern (figure 3.20). The higher the ratio, the better the antenna's interference performance.

As a practical matter, particularly in cellular network applications, lower sector power ratios indicate a higher amount of interference between antennas in adjacent coverage areas. When competing signals overlap, interference can increase and reduce performance, such as dropping a cell phone call while moving from one cell to another. Cellular networks require precise sectorized planning to prevent this kind of problem.

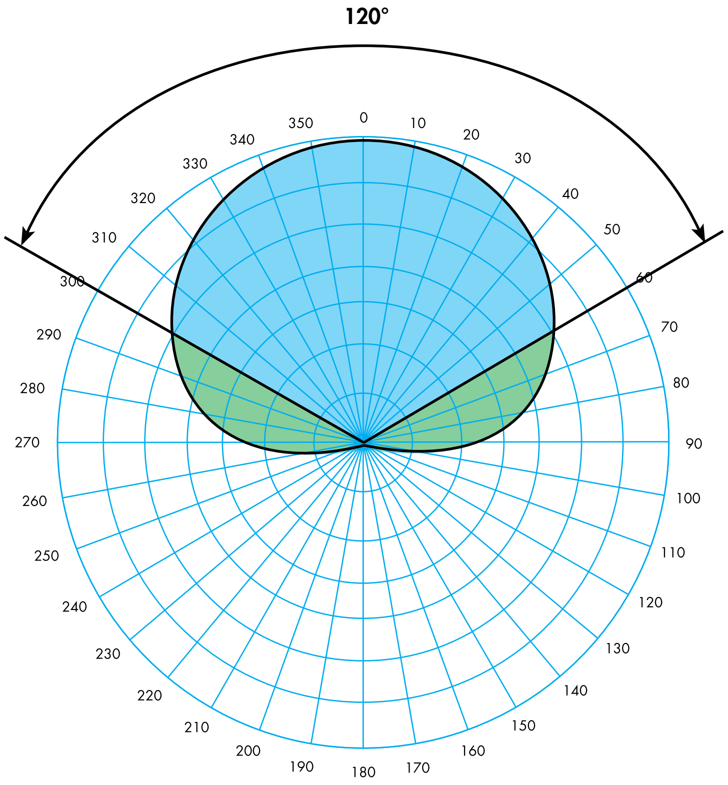
Beamtilt

As capacity requirements increase, one solution is to split the hexagons shown in figure 3.12 allowing the addition of more sites and reducing the coverage radius of the original site. To accomplish this, elevation beam downtilt is commonly used to reduce the gain on the horizon (and thus the coverage radius) as shown in figure 3.21. Mechanical downtilt results in undesirable pattern distortion on the horizon while electrical downtilt maintains the desired pattern shape.

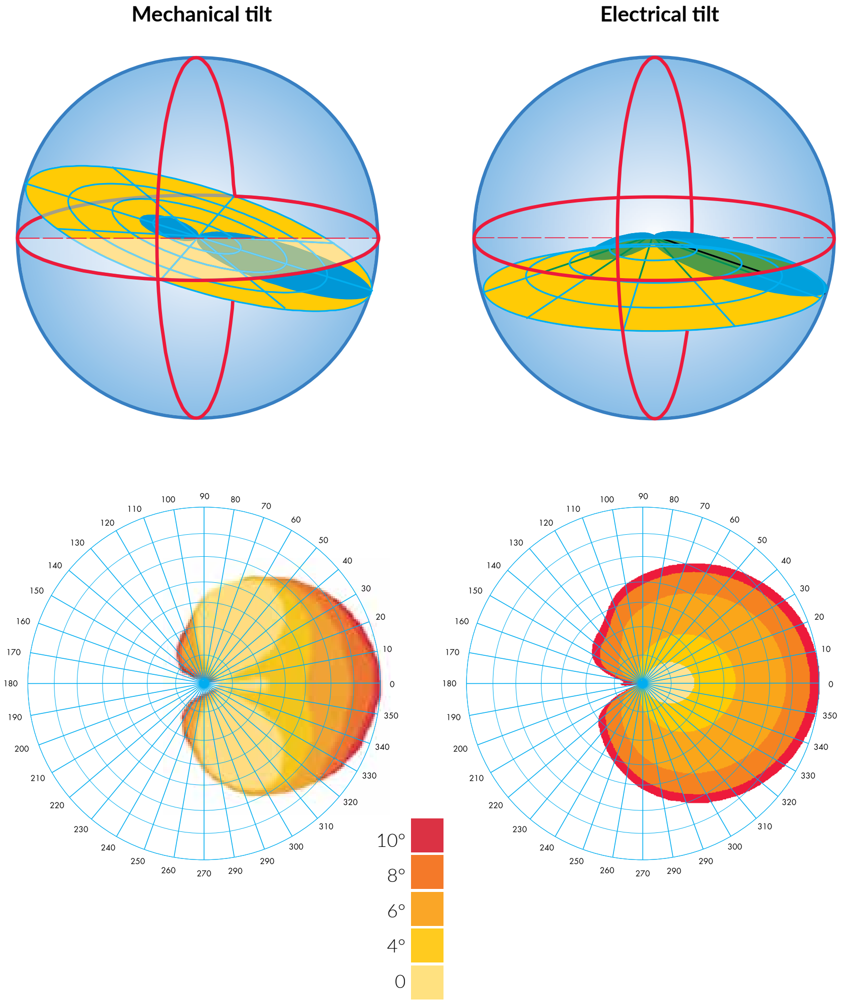
Early antennas incorporated fixed electrical downtilt, but this required multiple different models.

Cellular antennas on a practical level

When we move beyond the drawing board of theoretical antenna design to the real world, we soon discover that the laws of physics are not the only limiting factors affecting an actual installation. These issues include everything from tower weight and wind limits to local zoning board approvals for antenna size, shape, height and appearance. In most installations, compromises are necessary to satisfy all the competing interests.



3.20: Graphic and mathematical representations of an antenna's sector power ratio



Mechanical tilt

Electrical tilt

3.21: Tilting the antenna changes the shape of the lobe at ground level, reducing gain

Most cellular antennas are produced in a variety of physical sizes to offer the best performance while conforming to other requirements. Chances are that you've seen cellular antennas mounted in a number of ways, featuring diverse sizes and designs, such as the commonly used lengths of 4, 6 and 8 feet.

Materials and environment

Cellular base station antennas are only as reliable as the materials that go into their construction, and the construction of their arrays. When it comes to working with the physical limitations of an antenna's location, matching the right materials to the environment is a critical consideration. Here are just a few examples.

In the antenna array itself:

- Aluminum alloys offer lightweight strength, but can be vulnerable to the elements
- Pressure cast aluminum is well suited to bases, sockets, mounts and clamps, where its hardness and resistance to corrosion are critical
- In circumstances where weight is not a serious factor, copper and brass are used for their easy plating and conductivity properties

Antenna radomes:

- High-strength, low-RF loss materials such as fiberglass offer protection from the elements
- Materials must offer UV protection to prevent deterioration due to sunlight exposure

Tower appearance:

- For purposes of appearance and zone compliance, non-metallic paint can be applied to the entire structure
- For better wear, smooth surfaces should be roughed prior to painting

These are just a few of the more obvious physical considerations. Other matters in cable selection, connector choice and termination options demand close attention as well.

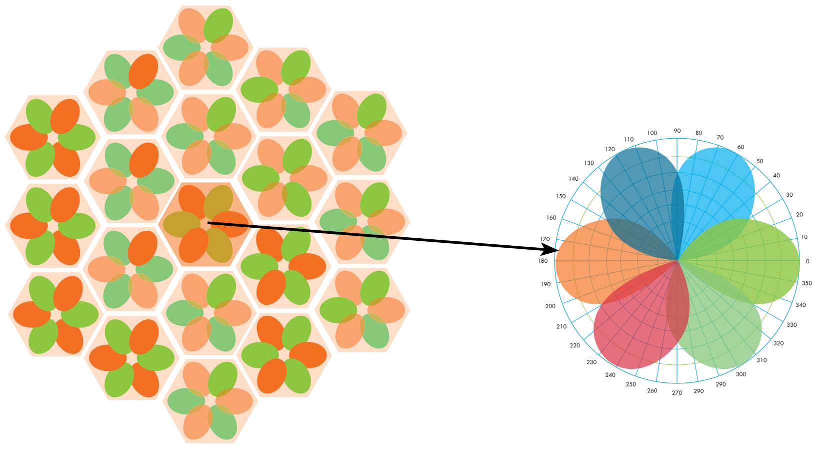
More capacity with fewer antennas

As mentioned earlier, cellular antennas are directional, often covering 120 degrees, or one-third of a complete circle. Mounted together on a triangular tower, three sets of these antennas can cover all directions. But in densely urban areas that require more capacity, narrower focus-antennas (called a six-sector scheme) can handle additional traffic along with the cost of adding more antennas. Having so many antennas in a single location makes it more likely to run afoul of local zoning codes.

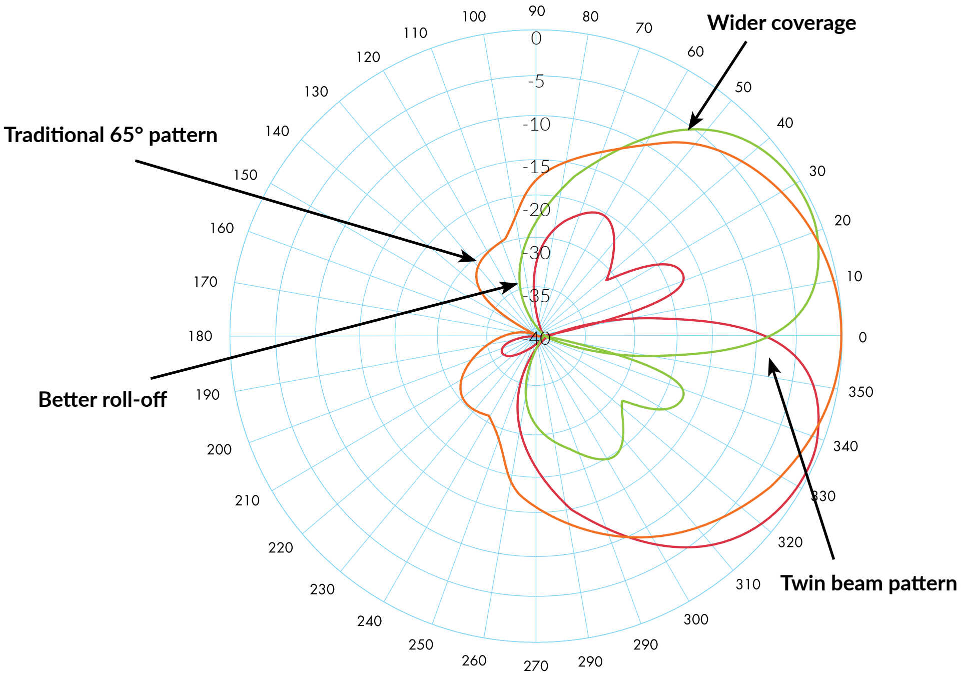
TwinBeam

One recent solution to this problem involves the TwinBeam antenna from **CommScope**, which produces two separate 35-degree beams with centers separated by 60 degrees. As the illustration below shows, this dual-lobe approach provides excellent coverage and, unlike the six-sector solution, only requires three antennas instead of six (figure 3.22).

'Six-Sector' sites



65° Antenna vs. Twin Beam antenna



Twin beam advantages

- Back-to-back broadcast channel (BCCH) re-use capability
- Enhanced RF footprint (higher gain)
- Better interference containment (better roll-off)
- Easier zoning and faster site deployment

3.22: Same number of antennas, double the coverage—a six-sector pattern compared to TwinBeam installation

SmartBeam®

Another type of antenna addresses growing capacity needs by intelligently steering themselves for maximum efficiency.

The **CommScope** solution is called SmartBeam. In addition to electronic downtilt, these multiple-degree-of-freedom antennas incorporate azimuth beam steering plus or minus 30 degrees and azimuth beam adjustment from 35 to 105 degrees (figure 3.23).

Shannon's Law

Created by Claude Shannon and Ralph Hartley, this law establishes a theoretical limit to how much data can be reliably pushed through a given amount of bandwidth.

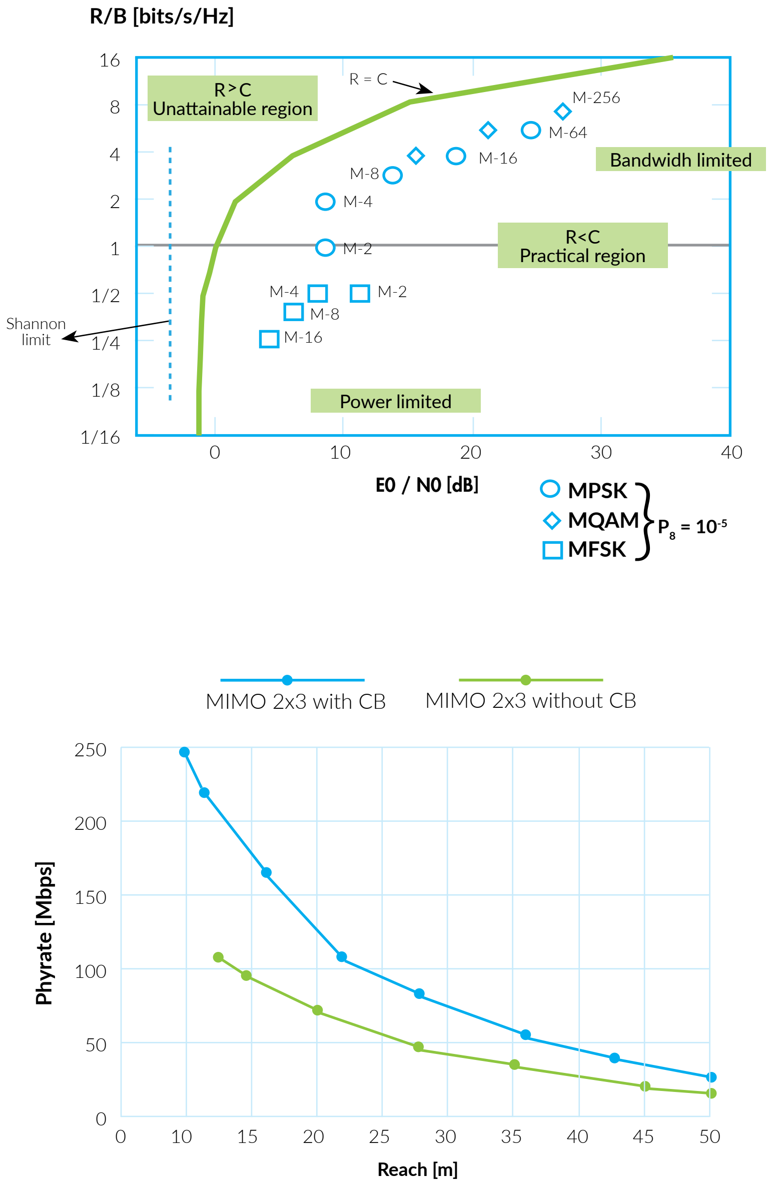
Adaptive array

A third capacity-boosting option incorporates several vertical elements that steer a beam toward each user on a tightly managed time-division basis. In this application, each user owns a particular time slot to move his or her traffic. Of course, managing this system for a large number of users requires powerful and sophisticated digital processing, but it also holds the potential to effectively "null out" nearby interference for better high-speed throughput (figure 3.24).

The next evolution

New technologies are being developed and deployed at a dizzying rate. The current field of cutting-edge networks is collectively known as long-term evolution networks (LTE). LTE has the potential to completely reshape how networks can perform, because it incorporates a concept called multiple input, multiple output (MIMO), which splits data transmission into multiple streams and sends them at the same time on the same frequency using multiple de-correlated RF ports. The expression 2x4 MIMO means that there are 2 de-correlated paths in the downlink and 4 de-correlated paths in the uplink.

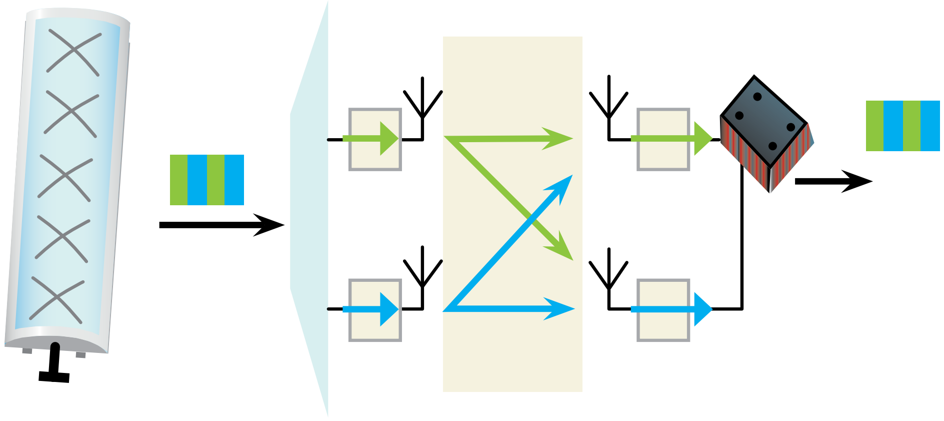
What makes this development so exciting is that MIMO offers a way around a classic limiting factor of RF communications known as Shannon's Law, which dictates how much throughput can be delivered down a given amount of bandwidth. As figure 3.24 shows you can only expect to get to within 3 dB of a bandwidth's theoretical maximum in a practical application.



3.24: A traditional plot of Shannon's limiting law

MIMO circumvents this limit through digital signal processing (DSP), which can distinguish between the two split signal paths and reassemble them into the original data on the receiving end. This workaround literally doubles the theoretical limits defined by Shannon's Law when applied in a 2x2 MIMO configuration with two transmit and two receive antennas (figure 3.25). It is quadrupled in a 4x4 MIMO configuration with 4 transmit and 4 receive antennas. Actual throughput improvements do not quite achieve this degree of volume, but that differential is to be expected in any practical application of theoretical performance.

MIMO systems
2 x 2 SU-MIMO: Spatial multiplexing



Same time and frequency resource

- Multiple input multiple output
- Capacity gains due to multiple antennas at both ends of the link
- Multipath provides additional channel using DSP
- LTE supports 1x2, 2x2, 4x2, 4x4
- Spatial multiplexing requires a multi-path environment

Different data streams

- Space Time Block Coding is a transmit diversity mode used S/N cannot support Spatial multiplexing
- Decorrelation between antennas and propagation paths required for Spatial multiplexing
- A dual polarized BSZ for 2x2 MIMO; two separated for 4x2 or 4x4 MIMO
- Alternatively vertically polarized antennas can be used with spatial separation

3.25: This 2x2 MIMO system uses digital signal processing to circumvent theoretical throughput limits

The basics of base station antennas

Incredibly diverse and remarkably efficient, antennas are the most critical link in any communications network. Radiating radio energy into space and collecting it from space, they can connect a single network backbone or thousands of individual users.

By virtue of their design, antennas can cover virtually any desired area of any shape. But it takes a lot of insight, knowledge and planning to get the most out of every watt. It all comes down to understanding your application's needs and its limitations.

With your new understanding of how antennas work, and how their performance is measured and compared, you may think twice the next time you are searching for more “bars” on your cell phone or a faster Wi-Fi connection for your computer. Then look up at the next TV aerial or cell phone tower you see and remember the complexity of the invisible processes that make modern communications possible at home, at work and on the go around the world everyday.

Chapter 3 summary

Antennas:

- Structures that radiate and receive radio energy
- Can achieve 80 percent efficiency or greater
- Directional (sectorized) or omnidirectional

Performance characteristics:

- Radiation pattern
- Polarization
- Gain
- Aperture

Enhancements through design:

- Vertical stacking
- Element spacing
- Horizontal pattern shaping
- Downtilt

Cellular base station antennas:

- Sectorized, grouped antennas commonly covering 120 degrees or less
- MIMO and LTE technology represent next step in speed and reliability

Working within the limits: Co-siting solutions

If you've ever tried to get more use out of the space in your home by combining a home office with a guest bedroom, you may not have been entirely satisfied with the results. Sure, you've saved space by making one room do the job of two, but you probably found that it can't do either job quite as well as a dedicated space would have allowed.

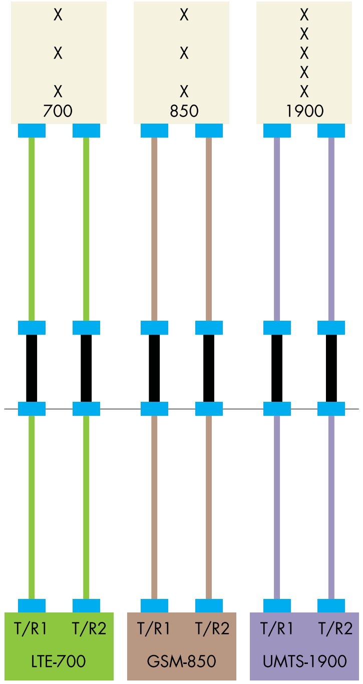
This tradeoff of space for utility is also the guiding principle behind co-siting a cellular installation. With space at a premium, there are real incentives to reducing your equipment footprint but every square foot saved places new constraints on the way that base station operates. Since every site has unique limitations, it can be a challenge to identify and implement the best *co-siting solutions*.

Whatever the specifics of a given cellular installation may be, **CommScope** offers a wide range of solutions that meet virtually any installation requirement. It takes a combination of technology and insight to make the best of every situation.

Co-siting solutions
The technology and techniques that allow cellular base stations and air interfaces to share architecture and operate within limiting factors of their locations.

Dealing with the realities

Just as it would be ideal to have an unlimited number of rooms in your home for every possible purpose, it would be ideal for cellular base stations to be equipped with their own dedicated antennas and feeders at every cell site (figure 4.1).



4.1: Multiband sector with separate feeders

If such an arrangement were possible in every installation, the benefits could include:

- Individually optimized antenna pattern, azimuth direction and downtilt angle
- Minimal RF path loss and signal mismatch
- Reduced interference and intermodulation between systems
- The ability to perform maintenance on one system without impacting the others

Sadly, this arrangement isn't a practical option for most real-world designs. When a cellular base station makes the move from the drawing board to the tower installation, its design becomes subject to an incredible number of variables and limiting factors. Some of the more common limits are:

- Local zoning ordinances that restrict quantity, size and location of antennas
- The tower's structural weight limits and wind load restrictions
- Budget constraints that limit both the initial and ongoing costs
- Scheduling demands that require accelerated service rollouts

Making the most of every watt

To address these limits and wring greater performance from every watt of power, co-siting solutions can help different technologies operate on a single architecture. Even networks operated by competing companies can realize mutual benefits by sharing site equipment, much as competing airlines will honor each other's tickets in the event of flight cancellations. In fact, such sharing agreements are now the norm with consumers benefiting from the providers' reduced operational costs in the form of better transmission speeds and reduced cell phone and data bills.

Co-siting solutions are usually based on specific equipment and configurations designed to improve performance within a defined set of circumstances under a defined set of limitations.

Multi-band combining

One frequently used technique is called *multi-band combining*, a method of frequency multiplexing. It takes advantage of the fact that feeder cables are naturally well suited to being shared by multiple frequency bands. In other words, multiple base station services can be funneled into a single feeder cable that runs up the tower to the antennas. Those services can then be split away from that one cable directly beneath the antennas.

To visualize this concept, think of how you bundle your home or office computer's wires into a single plastic cable wrap; at one end, the cables separate into various ports on the back of your computer. On the other end, the cables separate into your keyboard, mouse, network and printer connections.

To achieve the benefits of frequency multiplexing, the feeder cable must be equipped with the correct combining devices. Two or more frequency bands can be combined using multi-band combiners. Multi-band combiners are often added to a system as separate components, but they can also be built directly into other components such as antennas.

Widely known as crossband couplers, these combiners may be referred to as diplexers (two frequencies), triplexers (three frequencies), and so forth according to the number of frequency paths involved (figures 4.2 and 4.3).

4.3: Shared feeders using triplex crossband couplers, with broadband antennas using diplex crossband couplers

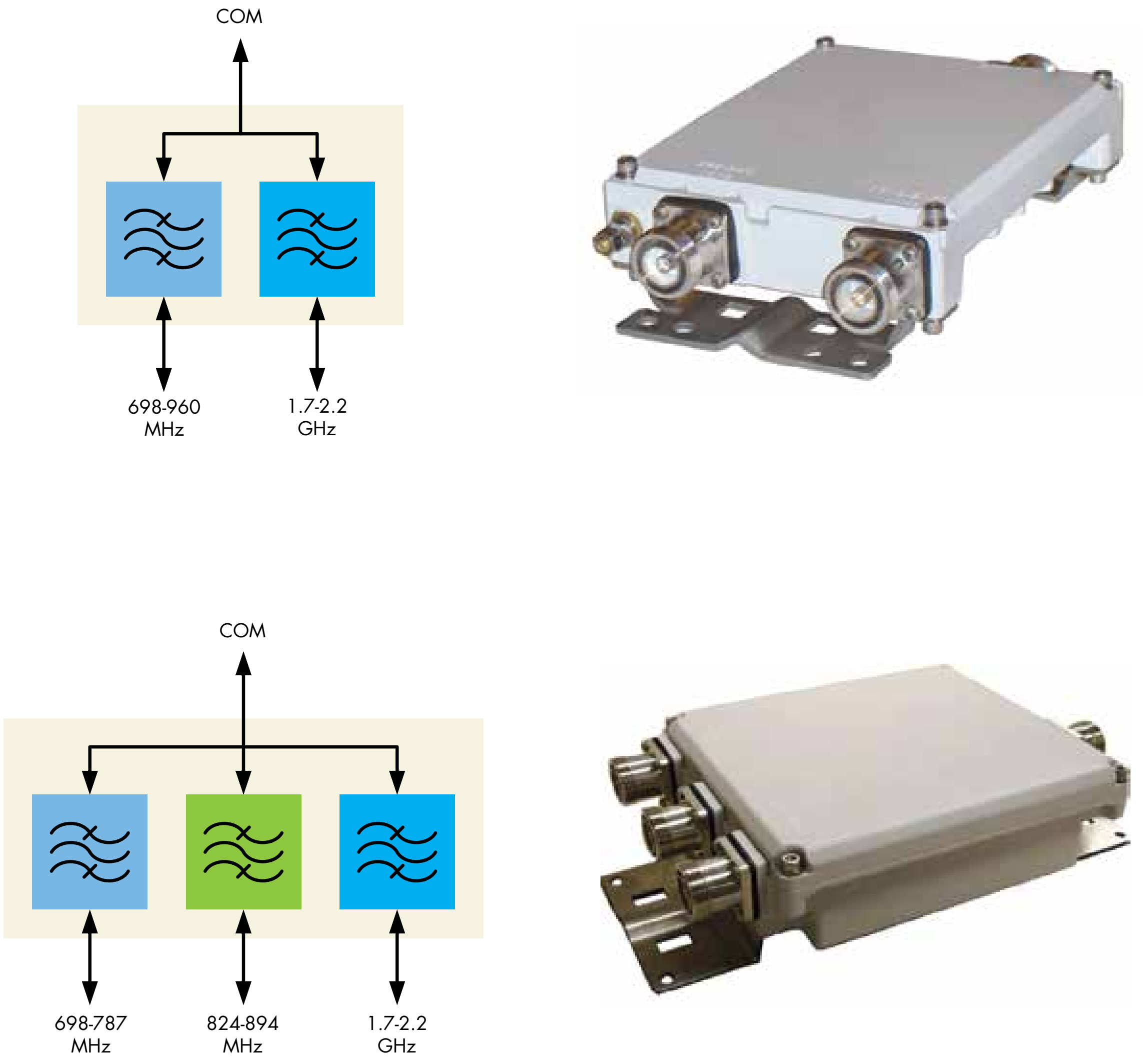
Multi-band combining
A configuration that connects multiple base station services that operate in separate bands to multiple antennas via a single feeder cable and its associated couplers.

The kind of crossband couplers required in a particular application is largely determined by the frequencies the system uses, and, more specifically, how far apart from each other those frequencies are. In systems with wide frequency separation such as 700-1000 MHz, 1700-2200 MHz and 2400-2700 MHz the needed crossband couplers are likely to be low-cost, compact devices that introduce virtually no loss or mismatch.

However, when dealing with frequencies that are relatively close to one another, such as 700 MHz and 850 MHz, the appropriate crossband coupler grows more complex, bulky and expensive (figure 4.4).

On the antenna side of the connection, additional efficiencies can be gained among broadband antennas that can accept more than one frequency through a single port. This allows it to operate over a range of bands through one feeder cable, as shown in figure 4.3.

Like the other circumstances involved in planning an efficient and compliant base station site, antenna selection and the base stations' assigned frequencies can play a large part in how a particular co-siting solution comes together.



4.4: Compact diplex and triplex crossband couplers, with example frequency differentiation

Same-band combining

In some instances, multiple services require the use of the same frequency band. When this happens, regular crossband couplers, which are designed to suit specific frequency separation, don't provide the solution we need. Instead, we can use a variety of *same-band combining (SBC)* options, which can allow different services to share the same space on the electromagnetic spectrum.

In some applications, same-band combining is even used for single-service systems—not to allow other services, but to increase the channels available to the one operating service. In all cases, the idea is to combine transmit signals (TX) and divide receive signals (RX). The best way to achieve this depends on the specifics of the application.

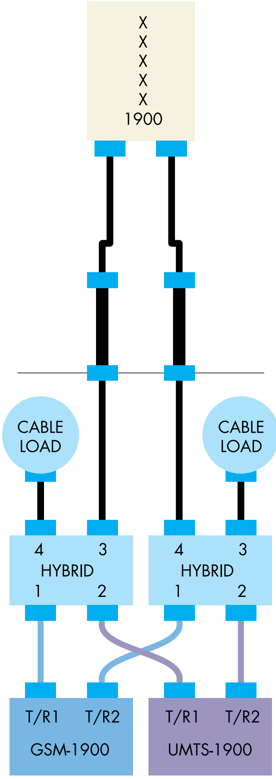
Now let's look at some of the more commonly used techniques.

Hybrid combining

Hybrid combiners offer a low-cost means of combining TX signals and dividing RX signals (figure 4.5), but this advantage comes at the cost of other operational restrictions inherent in its design.

The main disadvantage of this technique is the high rate of loss experienced in both directions. This loss increases with the number of ports involved, so hybrid combiners are generally used only in two-port applications.

Another consideration is the significant heat it generates which must be dissipated, adding costs and creating even more design limitations. These drawbacks limit the practicality of hybrid combining to in-building coverage and similar uses. It is rarely used in cellular sites.



4.5: A hybrid combiner, using cable load to lower passive intermodulation

Same-band combining (SBC)
A base station configuration that allows multiple services to share the same bands.

Guard bands

Narrow gaps inserted into the bandwidths managed by the LLC to distinguish different signals riding on the same bands.

Low loss combiner-multiplexer

The low loss combiner (LLC) offers a different way to combine base station transmitters. Commonly employed for combining TX signals, integrating a duplexer allows for distribution of RX signals as well (figure 4.6).

Like crossband couplers discussed earlier, the LLC is a filter multiplexer. However, unlike a crossband coupler that requires spaces between bands—you'll recall that the bigger the spaces, the better the coupler operates—the LLC handles frequencies inside the same bandwidth.

This is possible due to the addition of guard bands, which act as very small gaps within the band. They create boundary spaces between the frequencies, allowing them to be distinguished from one another.

Including these tiny *guard bands* often requires those narrow frequencies to be left unused, which adds up to slight bandwidth loss. In LLC design, smaller guard bands incur greater cost, size and complexity, so an economical alternative is to re-use the "lost" guard band space with a second feeder and antenna.

LLC design significantly reduces insertion loss over that of a hybrid combiner, but its reliance on filter multiplexing places significant restrictions on its scalability. As technology develops, networks require constant upgrading, adjusting and scaling which often means the adjustment or replacement of the LLC component. Recent developments in remotely tuned LLC hardware have helped reduce this limitation, but it remains a significant drawback for many applications.

Several examples of LLC realizations are shown in figures 4.7 and 4.8.

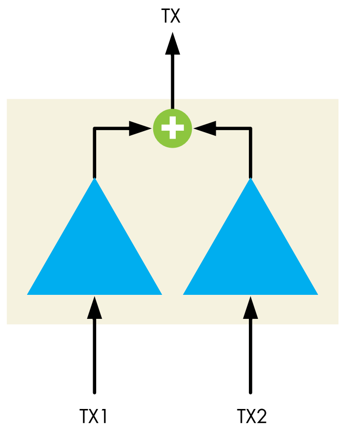
Amplification

Another technology that makes co-siting possible is amplification. There are several ways amplification can be used in support of the devices listed above, expanding their utility, power and range.

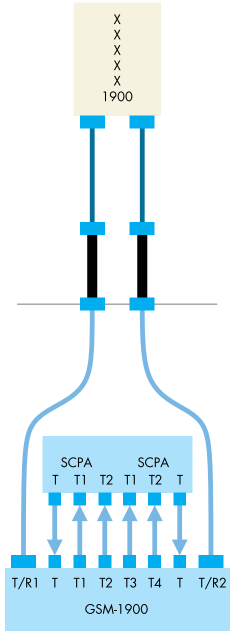
Single carrier power amplifier. You will recall that one of the hybrid combiner's drawbacks was its high rate of insertion loss for both TX and RX signals. One way to compensate for this is to add a single carrier power amplifier (SCPA) (figure 4.9).

The SCPA is highly efficient in regard to power consumption, but is only suited to certain engineering standards, such as the Global System for Mobile Communications (GSM) established by the European Telecommunications Standards Institute (ETSI). Still, in those applications where the SCPA is appropriate, the SCPA offers a low-cost means of improving hybrid combiner performance (figure 4.10).

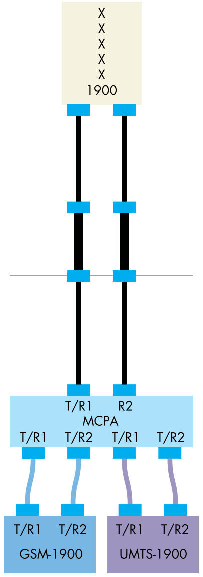
Multi-carrier power amplifier. Like the SCPA, the multi-carrier power amplifier (MCPA) is a high-power amplifier for carrier signals. Unlike the SCPA, however, the MCPA can also combine multiple RF signals into a single output. Its input circuits can be expanded to accommodate from two to eight ports, and sometimes even more (figure 4.11).



4.9: An SCPA module amplifies and combines two transmitters into one path



4.10: An SCPA installed between radios and BTS duplexer



4.11: An MCPA with integrated RX distribution

The MCPA's strong suit is boosting transmit power to increase the coverage or capacity of a particular base station. It also offers complete frequency agility, allowing free use of all frequencies within a license band. This makes it a very easy system to interface to other technologies. Its design generally incorporates one or more amplifier "bricks" working in parallel to provide the necessary power (figures 4.12 and 4.13).

An MCPA's demanding power consumption is its most notable drawback, which leads to elevated implementation and operational costs.

Receiver multicoupler. As its name implies, the receiver multicoupler (RXMC) distributes RX signals from shared antennas to multiple receivers. By splitting the signal this way, a natural side effect is some loss of power. To compensate, the RX input first crosses a low-noise amplifier (LNA) which preserves signal strength, preceded by a preselector filter. Inclusion of an LNA is recommended for most applications with more than two receivers.

As a rule, the RXMC distributes the full RX frequency band to all outputs with the same degree of gain across the board. To individualize distributions, the RXMC may allocate specific signal strength to each receiver by unequally dividing the gain. This is a useful option when dealing with different locations, or with a receiver that will further divide its signal to other receivers down the line.

Tower-mounted amplifiers. Working with these other co-siting solutions, a tower-mounted amplifier (TMA) improves the base station's sensitivity the same way a hearing aid can improve diminished hearing. It works to offset the losses experienced by RX signals as they travel to the receiver. This improvement in signal clarity is seen in the carrier-to-noise ratio (C/N), measured in decibels (dB). Adding a TMA to the RX circuit on a cellular base station can yield a typical improvement of 5-6 dB.

TMAs are a key part of RF path technology. Properly implemented and configured, they improve:

Coverage. They boost the effective service radius of a cell base station while improving signals in weak spots, such as indoors.

Accessibility. They significantly reduce failed access attempts.

Retainability. They improve a site's retainability, or its ability to maintain connections within and across cells for fewer dropped calls.

Co-channel interference. They improve call capacity in spread spectrum systems.

Data throughput. They enable higher order modulations for increased traffic capacity.

Handset battery life. Because less power is required from the cell phone's transmitter, TMAs prevent unnecessary battery drain.

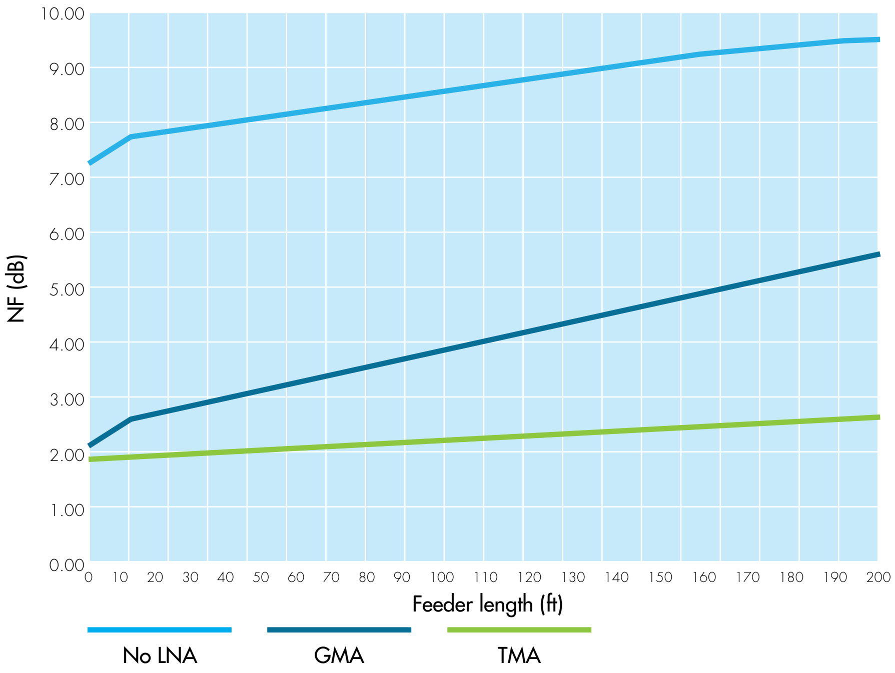
With the right adjustments, TMAs offer all these advantages that help operators enhance their network capacity and coverage.

TMA benefits

To gain the maximum advantage, it is important to boost the RX signal level before it becomes degraded by feeder loss between the tower and the base station receiver. This is the reason the TMA should be mounted at the tower top, as close to the RX antenna as possible.

An LNA may also be installed at the ground level and is then called a ground-mounted amplifier (GMA). When it reaches the GMA, the RX signal will already be weaker and noisier than it originally was at the antenna. Therefore, the sensitivity improvement a GMA can provide is limited at it's improving an already weakened signal. On the other hand, its main advantage is that it is easier to install than a TMA, and does not occupy precious tower space. Because it doesn't introduce the size and weight concerns of a tower-mounted TMA, the GMA design can focus on performance. Superconductors and cryogenic cooling can be used to maximize performance and partially offset the disadvantage of its ground-level location.

Many factors contribute to feeder loss. Smaller cable diameter, longer feeder runs, and higher operating frequency all influence performance, and the TMA offers a single method of offsetting all these factors with one remedial measure. You can see how TMA and GMA implementations affect the noise levels in a system in figure 4.19.



4.19: Noise figure in a system with no LNA, with a GMA and with a TMA; the superior performance of the TMA is evident in its lowest noise figure

TMA configurations

As explained in our earlier look at the receiver multicoupler (RXMC), a tower-mounted amplifier employs an LNA (with a preselector filter) to boost signal strength to compensate for division loss. Since modern TMAs often employ a dual duplex configuration, which allows the use of duplexed feeders, two additional filters are needed to pass the signals between the BTS and antenna.

Dual-band TMAs are essentially a pair of single-band TMAs integrated into one device. Some types feature separate RF paths for each band, while others diplex the bands into a single path at the BTS port or at the ANT port. Interestingly, diplexers can also be integrated into single-band TMAs to offer an additional, non-amplified path. These devices are called *bypass or pass-through configurations*.

As a result of growing demand for reliable cellular network service, coupled with frequent restrictions on the amount of equipment permitted on a particular cell site, dual-band TMAs are becoming more and more popular as a co-siting solution. You can see examples of some different TMA architectures in figures 4.20 through 4.26 beginning on this page and continuing on page 14.

Enhanced features: AISG

The *Antenna Interface Standards Group (AISG)* is comprised of representatives from the world's leading wireless equipment manufacturers and service providers, including **CommScope.** AISG's standards have led to improvements in remote control and monitoring of antenna downtilt, TMA alarms, and other important advances. Adoption of these protocols has advanced performance and assured interoperability between various systems—a major boon for co-siting solutions like the ones discussed above.

Contemporary co-siting components must accommodate AISG communication, whether they process the signals or simply pass them along to other devices. The AISG protocol currently includes procedures for monitoring and controlling TMAs, such as setting gain and reporting alarms. Additional procedures may be defined in the future to support a wider range of "smart" co-siting devices that will help optimize performance, enable remote supervision of the RF path, and reduce cost of ownership.

Antenna Interface Standards Group (AISG)

Founded in 2001, the AISG represents more than 40 top manufacturers and service providers from all over the world. AISG publishes universally accepted industry protocols for communications between base stations and tower-based equipment, such as antennas and TMAs.

Making the most of available space and power

The design of a cellular communications system reflects many choices and compromises. The result is that no two are exactly alike. Certain preferred characteristics come at the expense of other characteristics; those choices are always made with an eye toward conserving space, reducing costs and operating within constraints.

By employing the kind of innovative solutions discussed in this chapter, wireless operators are able to improve service and reduce costs by working together to share infrastructure wherever possible. We see the benefits in the form of lower cell phone bills, clearer and more reliable calls, and faster data downloads and Web surfing on our mobile devices.

Chapter 4 summary

Co-siting solutions:

- The technology and techniques that allow more performance in less space
- Driven by limits on amount, weight and cost of base and antenna-mounted equipment

Multi-band combining:

- Leverages feeder cable's capacity for multiple frequencies
- Requires frequencies in separated bands
- Uses crossband couplers in diplex, triplex or more complex configurations

Same-band combining:

- Hybrid combining: inexpensive but lossy
- Low loss combiner: efficient but constrained frequency applicability

Amplification:

- Single carrier power amplifier: low cost, high efficiency, limited applications
- Multi-carrier power amplifier: scalable, flexible but expensive to install and operate
- Tower-mounted amplifiers: broad-based receiver performance boost

Chapter 5

Talking and listening at the same time:
Transmission and receiving isolation systems

Right now, millions of people around the world are downloading music, surfing the web, texting, talking and listening on their mobile devices. It's probably safe to say that they are *not* thinking about the science or technology that enables every download, text or conversation. Mobile devices are simply a way of life.

Here at **CommScope,** we're continually fascinated by the technical innovation and principles behind wireless communication. Take transmission and receiving isolation systems, for example. Unlike conventional landline phones, cell phones are actually radio receivers and transmitters, so maintaining simultaneous two-way communication—talking and listening during a call—is more complex than it appears.

Duplex communications
A transmitter and receiver that work at the same time on the same RF device.

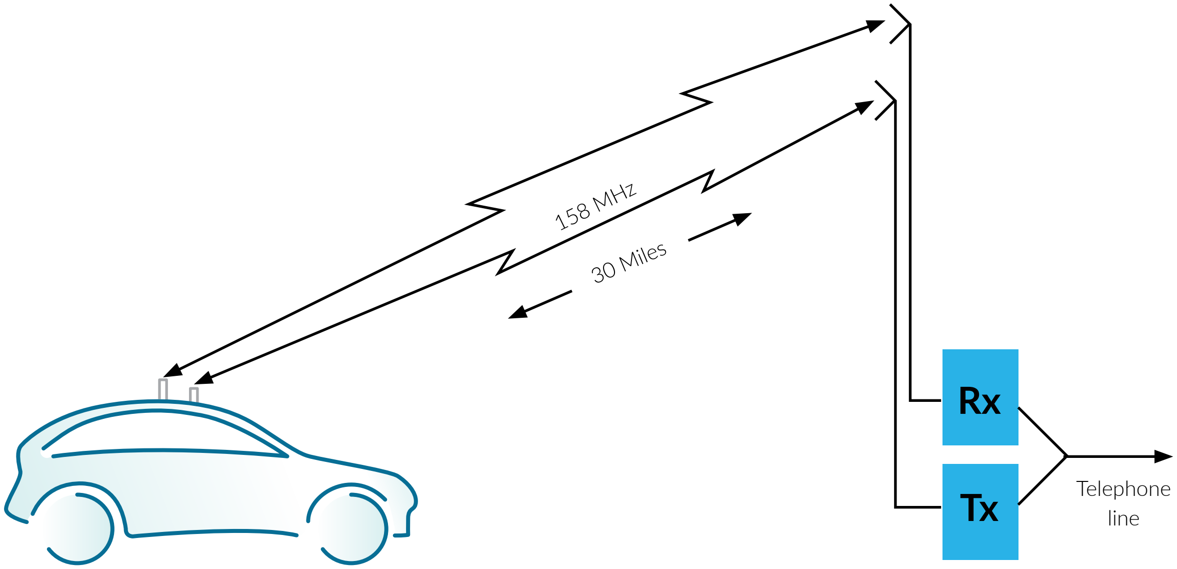
Isolation
The amount of separation achieved between the transmitter and receiver in a duplex communication system. In general, more isolation translates to less interference and clearer communications.

An RF communications system that employs this simultaneous, two-way flow of voice, data or other information is called a *duplex system*. Duplex communications systems combine multiple transmit and receive channels on a shared antenna, with information flowing both ways at the same time.

Imagine the simultaneous flow of traffic on a busy two-way street. You immediately see the importance of keeping the two different directions of traffic separated. Just as vehicles on a busy, two-way street require clear lane markings to avoid collisions with oncoming vehicles, duplex RF channels also must be “isolated” from each other to avoid interference.

In RF terms, *isolation* is measured as the loss between two channel ports, either transmitter-to-transmitter or transmitter-to-receiver ports. The higher the loss, or isolation, between the two ports, the cleaner the signal.

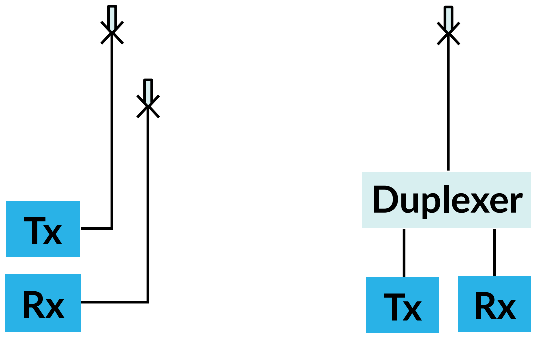
To illustrate this concept, think about making a cell phone call from your car. This simplest of duplex systems—one transmitter and receiver pair communicating with another transmitter and receiver pair—requires that both the phone and receiving station be able to receive and transmit at the same time, allowing a normal telephone conversation to take place (figure 5.1).



5.1: Duplex operation between two pairs of transmitters and receivers

To allow this communication to flow on a single antenna, a *duplexer* must be used with adequate isolation measures (figure 5.2). Measured in dB, isolation is a critical consideration in the design of any duplex system. Without proper isolation, a transmitter will adversely affect the performance of its associated receiver, even though they may operate on different frequencies.

Duplexer
A device situated between a duplexed antenna and its associated transmitter and receiver. A duplexer's function is to provide isolation between the signals.



5.2: Two solutions: Use two antennas, or a single antenna with a duplexer

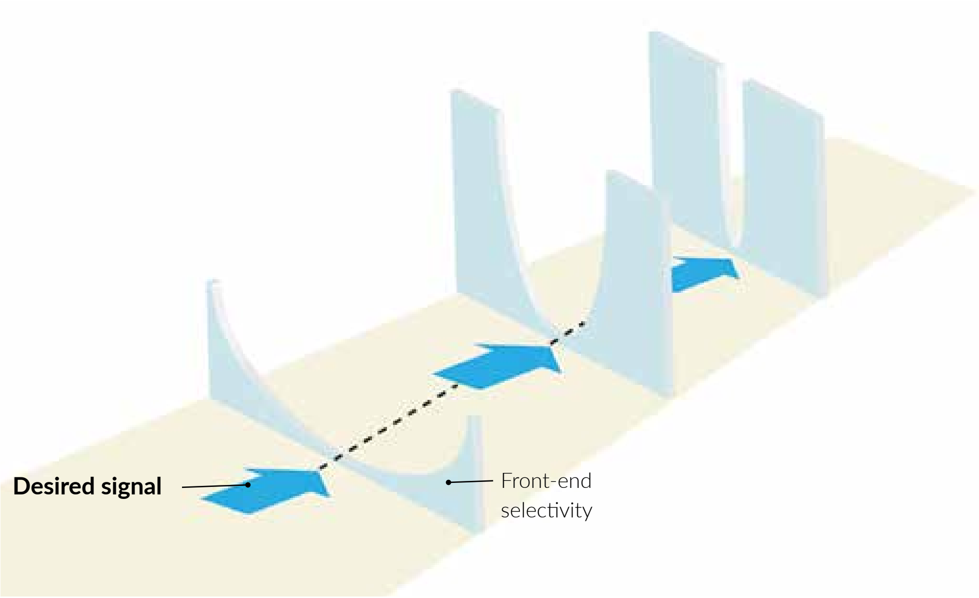
The specifications covering a particular receiver, for instance, may indicate that any RF signal outside the receiver's passband (which can be as narrow as 15 kHz) will be attenuated, or weakened, by as much as 100 dB. That means that the transmission's power will be reduced to 1/10,000,000,000th of its original strength, making the communication unintelligible and useless in most cases.

You might think that such a selective receiver would prevent interference from a transmitter operating on a frequency far outside the receiver's passband. After all, if the interfering signal is 5 MHz away, how could it create complications when just being 5 kHz off the mark reduces the transmitter's signal to virtually nothing? The answer lies in the characteristics of modern receivers, and the way they can step high-frequency signals downward to achieve such precise frequency selectivity.

Receiver desensitization
Interference caused by unwanted frequencies entering a receiver's upper-stage passbands. These errant signals create electrical variances that impede the receiver's operation.

The first challenge: receiver desensitization

Receiver desensitization is an inherent side effect of modern receiver design, which receives relatively high-frequency signals (often between 700 MHz and 3500 MHz). These signals pass through frequency-lowering stages in the receivers, which allow the receivers to feature such narrow, selective passbands (figure 5.3). Once the signal has been lowered enough, only a small band remains and the circuitry can reject other bands within a margin measured in dB. A receiver's specification sheet will include this measurement of overall selectivity.

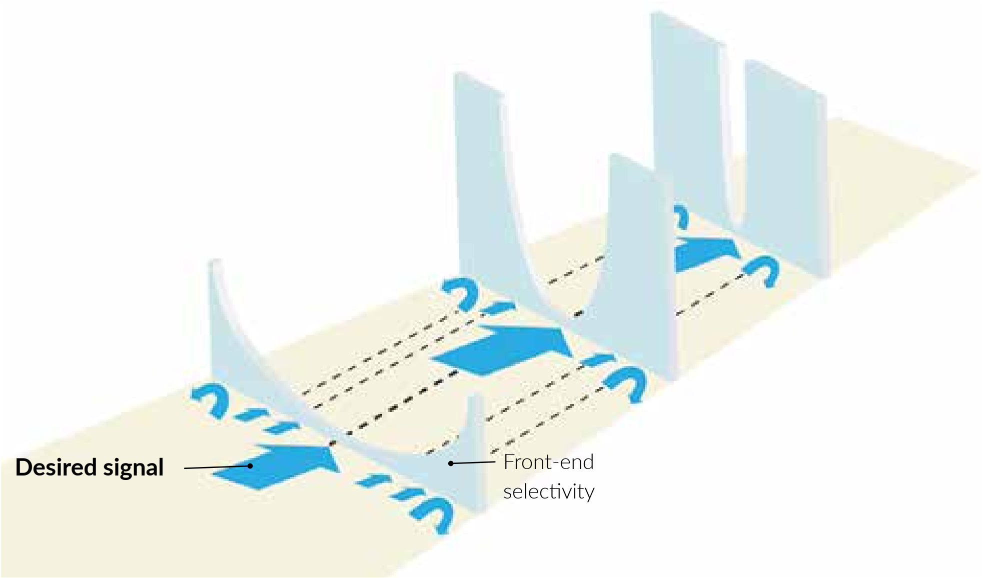


5.3: In a receiver, high-frequency signals are reduced in stages

The vulnerability is not at the end of this reducing process, but at its beginning. Remember that the initial signal was of higher frequency, and only after multiple stages of reduction was it lowered to the point where the receiver could use it. The receiver's earlier, broader stages cannot completely reject errant signals, even those several MHz away from the receiver's operating frequency.

For optimum performance, critical voltage and current levels exist at certain points throughout the front-end stages of a receiver. If these levels change significantly, the performance of the receiver suffers. This happens when a nearby transmitter's off-frequency signal enters the front-end stage.

Such signals can be several MHz away from a receiving frequency, and radiate from sources several thousand feet away, and still cause significant interference (figure 5.4).



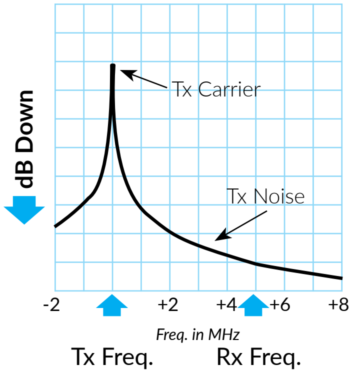
5.4: Unwanted frequencies (shown here as reflected arrows) can alter critical receiver voltage and current levels

Transmitter noise
Interference experienced by a receiver as a result of transmission power "leaking" into other nearby frequencies.

The second challenge: transmitter noise

Transmitter noise is interference caused by carrier signals just outside of a transmitter's assigned frequency. In an ideal world, a transmitter would channel 100 percent of its signal power into the narrow band of frequencies assigned to its transmission channel. In the real world, however, this level of precision is simply not possible, and the result is called transmitter broadband noise radiation, or more commonly, transmitter noise. While the vast majority of transmission power remains within the assigned channel, there remains a small fraction that "leaks" into channels above and below the intended carrier frequency.

Modern transmitters are equipped with filter circuits that eliminate a large portion of these errant signals, but even with these measures in place, enough transmitter noise escapes to degrade the performance of a receiver. As the chart below illustrates, this interference effect is most pronounced at frequencies closest to the transmitter's carrier frequency (figure 5.5), but can also impact receivers operating several MHz away.



5.5: Transmitter interference is most pronounced near the assigned frequency (shown here as Tx frequency, located at zero on horizontal axis)

We hear transmitter noise in a receiver as "on-channel" noise interference. Because it falls within the receiver's operating frequency, it competes with the desired signal and cannot be filtered out.

To illustrate this kind of interference, imagine having a conversation with someone in a crowded room. If everyone else is talking, you'll notice how hard it is to understand the other person, even if the overall noise level in the room is relatively low. That's because other voices, like unwanted transmitter noise, are similar to the voice you're trying to hear.

This is a key distinction between transmitter noise and receiver desensitization, which you'll recall comes from signals far from the operating frequency of the receiver. Consider again the illustration of having a conversation. Receiver desensitization is more like loud, disruptive sounds coming from a construction site next door. The interference is not similar to the voice you're trying to hear, but it still distracts you from the other person's voice.

How isolation helps duplex communications overcome both challenges

In duplex RF systems, transmitting and receiving frequencies are close to each other. In addition, the antennas will also be physically close, or even share a single antenna. Now that we understand the source and nature of the two interfering elements—receiver desensitization and transmitter noise—how can we overcome these interfering influences and assure reliable operation of our paired transmitters and receivers?

The answer, as you may have guessed, is proper isolation.

Earlier in this chapter, we explored how a duplex RF system required isolation between transmitter and receiver using the example of a call on a mobile device. But when applying that theory to practical application, adding isolation to the system requires some planning and a bit of math. Remember that we have not one but two sources of interference to overcome—receiver desensitization and transmitter noise—and each requires its own solution.

It boils down to two simple questions:

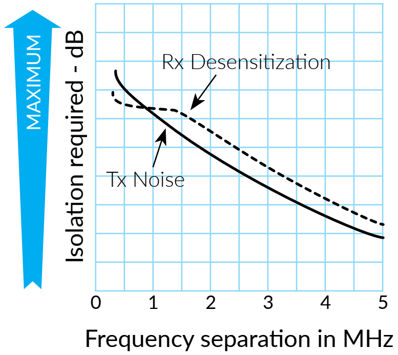
1. How much isolation is required **to prevent receiver desensitization** from the transmitter's carrier, and;
2. How much isolation is required **to reduce transmitter noise** to a lower, even negligible level?

While these are simple questions, each one has many more questions built into it, such as, but not limited to:

- How close together are the transmitter and receiver frequencies?
- What frequency band are we using?
- What is the transmitter's power output?
- What are the unique product specifications for the particular transmitter and receiver we're using?

While each application will have very different answers for these and other considerations, you can usually find the answers in the equipment manufacturer's data. For the purposes of this discussion, we'll focus instead on the broader use of isolation in duplex systems.

Determining the amount of required isolation is a matter of examining both sources of interference and identifying the optimal isolation level. As shown below (figure 5.6), we see the effect of frequency on both interfering influences, receiver desensitization (dotted line) and transmitter noise (solid line).



5.6: The effect of frequency separation on receiver desensitization and transmitter noise

In short, the closer the frequencies are to one another, the greater the need for isolation. For instance, the chart shows that reducing the frequency separation from 5 MHz to 1 MHz requires double the isolation to assure that the receiver will not be sensitized and that transmitter noise will be reduced to negligible levels.

Horizontal separation
The practice of placing a transmitter's antenna a certain distance from the same device's receiving antenna to achieve the necessary isolation.

Achieving sufficient isolation

Once we have determined the requisite amount of isolation by answering our specification questions and applying what we learned from figure 5.6, we can implement the correct degree of isolation by one of two methods:

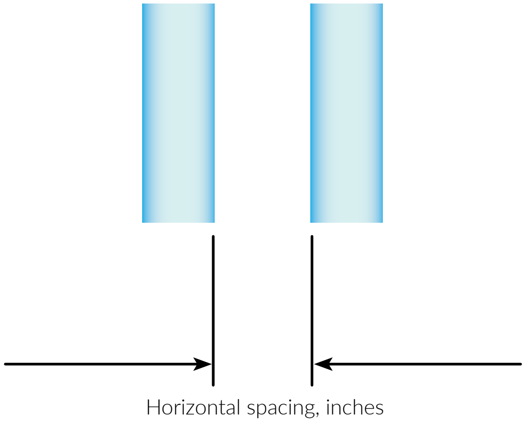
1. Use two antennas, physically separated by a given distance, or;
2. Use the appropriate duplexer with a single-antenna system.

Let's examine the first option of two physically separated antennas. Within this option, there are two ways of achieving the desired result: horizontal and vertical separation.

Method 1: Two antennas—horizontal separation

If you've ever driven cross-country with the car radio on and heard a favorite song fade to static in mid-chorus, you've experienced an effect called propagation loss. Propagation loss describes the way an RF signal loses intensity and weakens (or attenuates) as it travels across distance. This effect means that placing the two antennas apart—creating *horizontal separation*—yields a certain amount of isolation, simply by virtue of signal attenuation in the space between them (figure 5.7).

With enough distance, we can achieve virtually perfect isolation and total protection from both receiver desensitization and transmitter noise. However, even the most isolated RF system is vulnerable to interference from outside sources located nearby.



5.7: Horizontal antenna spacing and isolation

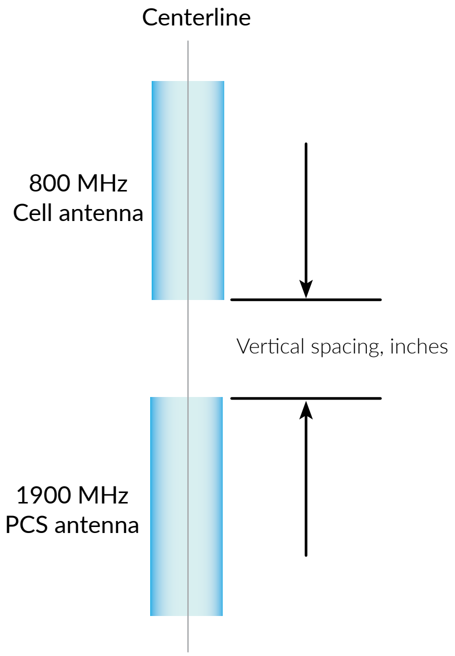
Method 1 alternative: Two antennas—vertical separation

Alternately, one may achieve the same isolating effect by separating the transmitter and receiver vertically, a practice called *vertical separation*. In real-world applications, this option is more convenient and efficient as it allows both transmitter and receiver to be mounted on a single tower, one above the other, separated by the requisite distance to achieve sufficient isolation.

A secondary benefit of vertical separation is that this arrangement takes advantage of what is known as the “cone of silence” that exists between vertically stacked antennas (figures 5.8A and 5.8B).

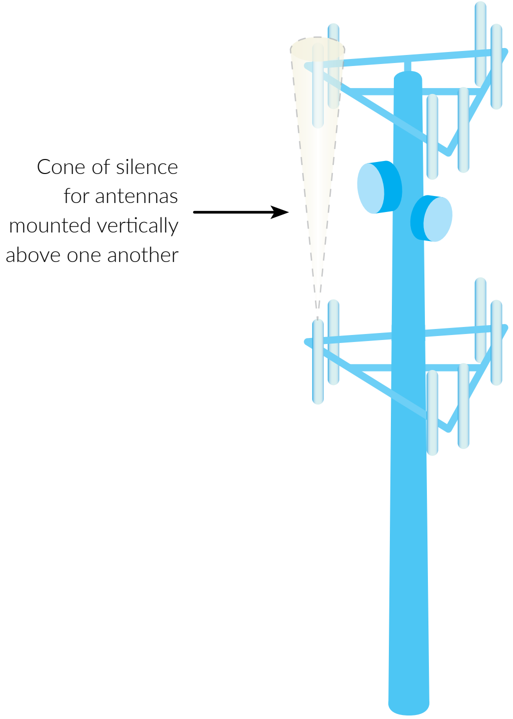
The cone of silence is a dead zone (technically known as a null or lack of gain) that extends above and below communications antennas, allowing each to operate in the other’s shadow, so to speak.

Vertical separation
The practice of placing a transmitter and receiver in separate locations on a single antenna, allowing the height difference to achieve the necessary isolation.



Centerline
800 MHz
Cell antenna
Vertical spacing, inches
1900 MHz
PCS antenna

5.8A: Vertical antenna separation and isolation



Cone of silence
for antennas
mounted vertically
above one another

5.8B: The “cone of silence” isolates antennas directly above and below each other

Comparing the characteristics of each quickly reveals the superiority of vertical separation in practical applications (figure 5.8C).

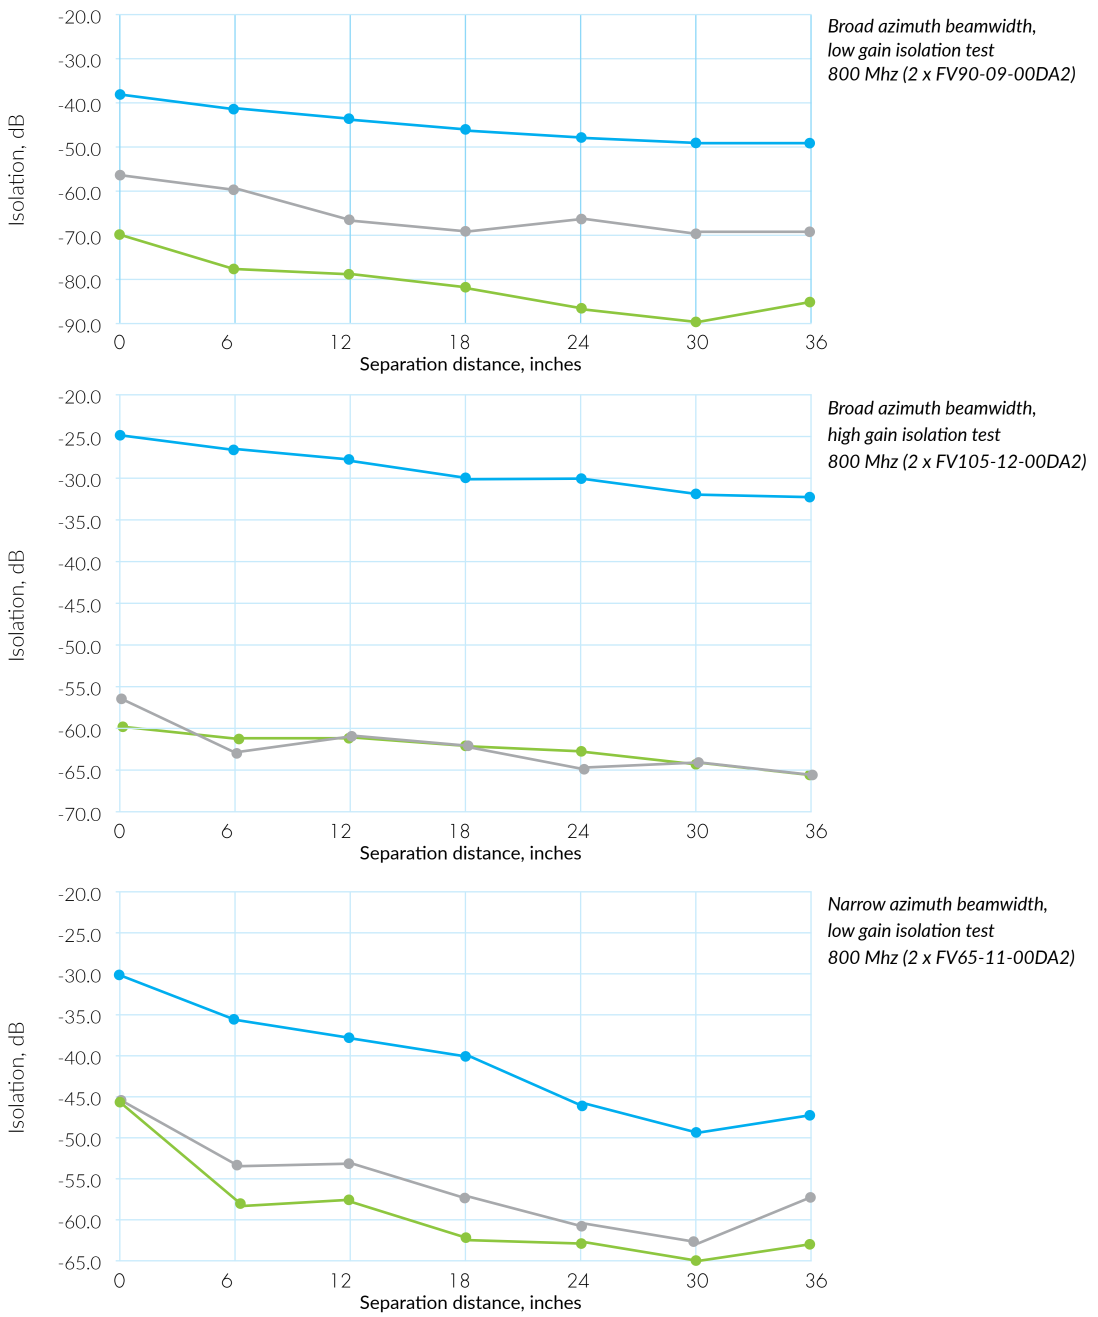
It should also be noted, however, that the effects of horizontal and vertical separation are not directly additive. In other words, using both methods on the same system will not yield the full, combined isolation of each. Antenna manufacturers can supply specific figures on what you can expect from combining methods in any particular application.

● Vertical spacing 0 deg d/t

● Vertical spacing 10 deg d/t

● Horizontal spacing 0 deg d/t

5.8C: Graphs at right describing attenuation (in dB) against separation (in feet) for both horizontally and vertically separated antenna pairs



Broad azimuth beamwidth, low gain isolation test 800 Mhz (2 x FV90-09-00DA2)

Broad azimuth beamwidth, high gain isolation test 800 Mhz (2 x FV105-12-00DA2)

Narrow azimuth beamwidth, low gain isolation test 800 Mhz (2 x FV65-11-00DA2)

Method 2: One antenna with a duplexer

The other method of achieving the required isolation between transmitter and receiver is the use of a duplexer in a single-antenna system. A duplexer replaces one of the two antennas and two lengths of coaxial cable by allowing both transmitter and receiver to operate at the same time, on the same antenna (figure 5.9).

The cost benefits from this option can be significant, as a duplexer cuts the needed infrastructure in half. But the cost benefits are secondary to the other advantages, including:

Isolation. A duplexer reliably isolates transmitter and receiver, regardless of external circumstances or terrain.

Antenna pattern. Without a duplexer, two separated antennas are required. Whether arranged in a horizontally or vertically separated configuration, they cannot occupy the same space. This separation means that the coverage area of either the transmitter or receiver may be larger or smaller than the other, a variable that a duplexer eliminates.

Tower space. Leasing tower space is expensive and space on the tower is at a premium. By building or leasing only one tower instead of two, operators can realize lower total cost of ownership.

These are all good reasons to opt for a single antenna with a duplexer, but, as with every advantage in engineering, there are drawbacks as well. We'll explore these considerations a bit further on, but, for now, let's examine how a duplexer actually works and how to choose the right one for a particular application.

5.9: A typical cell site duplexer configuration

Considerations in choosing a duplexer

There are two distinct families of duplexers used in two-way RF communications: the bandpass duplexer and the band-reject duplexer. To choose the right option, it's important to consider the requirements of the system and what the correct duplexer must do. For the best results, a duplexer must:

1. Be designed to operate in the system's frequency band
2. Be able to handle the transmitter's power output
3. Operate at or below the system's frequency separation
4. Create minimal power loss to transmit and receive signals
5. Provide at least a minimum level of transmitter noise rejection
6. Deliver sufficient isolation to prevent receiver desensitization

These last two factors relate specifically to isolation and prevention of interference. In both cases, protection must meet a minimum threshold, but there is no hard upper limit, and no harm in exceeding specified isolation levels.

Losses through the duplexer

As a matter of course, the signal strength of both the transmitter and the receiver are reduced slightly in the process of passing through the duplexer. These losses are called *insertion loss: transmitter to antenna* and *insertion loss: receiver to antenna*. Like losses caused by other forms of attenuation, these duplexer losses are measured in dB and tend to increase as frequency separation between transmitter and receiver decreases (figure 5.10).

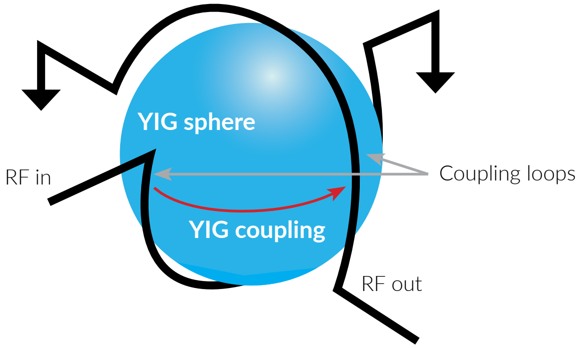
Insertion loss: transmitter to antenna	
Insertion loss	Reduced power (watts)
0.5 dB	11%
1.0 dB	20%
2.0 dB	37%

Insertion loss: receiver to antenna	
Insertion Loss	Reduced strength (microvolts)
0.5 dB	5%
1.0 dB	11%
2.0 dB	20%

5.10: Equivalent signal power loss at discrete duplexer insertion loss levels

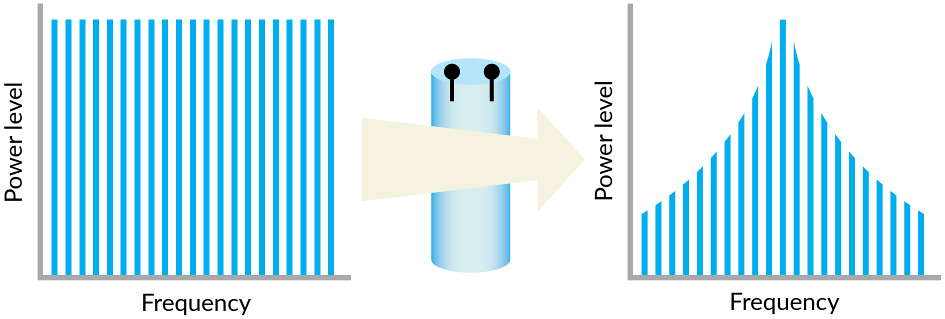
The bandpass cavity

The distinguishing feature of the bandpass duplexer's design is the *bandpass cavity*. The bandpass cavity works as a filter of RF frequencies, allowing a narrow band of desired frequencies to reach the receiver and attenuating frequencies outside this band. Energy is fed into the cavity by means of a coupling loop. This energizes the resonant circuit formed by the inner and outer conductors. A second loop couples energy from the resonant circuit to the output (figure 5.11). The loops determine the selectivity of the bandpass cavity.



5.11: The operation of a coupling loop

The narrow band of desired frequencies that pass through the cavity experience only slight loss and are all within a few thousand cycles of the cavity's *resonant frequency*. The effect of multiple frequencies, transmitted at equal power, on a bandpass cavity is illustrated below (figure 5.12).



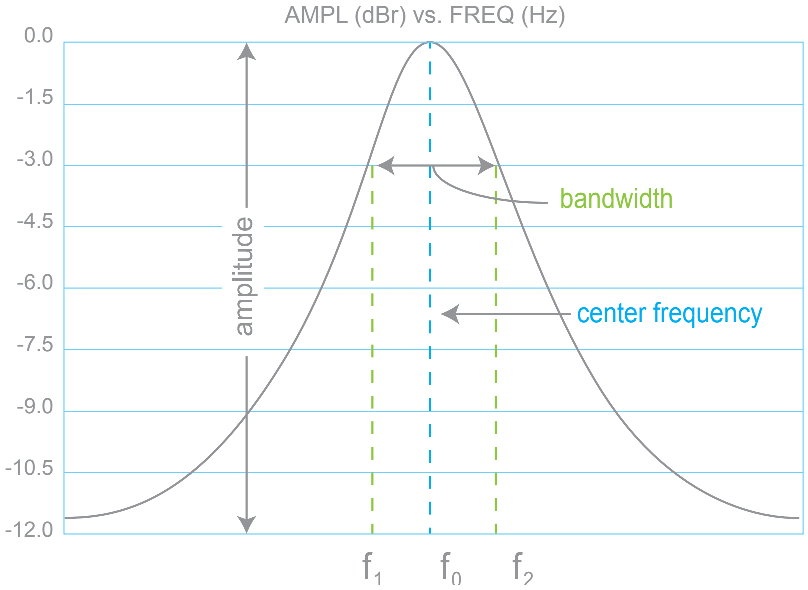
5.12: Attenuation of undesired frequencies passing through a bandpass duplexer

Bandpass cavity
A "frequency filter" that limits the channels that pass through the filter to a select set of frequencies. Other frequencies are prevented from passing. Most devices have multi-stage bandpass cavities that filter out different frequencies at each stage.

Resonant frequency
The natural tendency of a system to oscillate with larger amplitude at particular frequencies. At these frequencies, even small periodic driving forces can produce large amplitude oscillations.

The selectivity of a bandpass cavity is usually illustrated in a frequency response curve. This curve describes the degree of attenuation provided by the cavity at discrete frequencies above and below the cavity's resonant frequency. The curve also shows the insertion loss to the desired signal at the cavity's resonant frequency (figure 5.13).

In cases where a single bandpass cavity cannot provide enough rejection to undesired frequencies, the addition of more cavities in sequence can further refine selectivity. While this results in additional insertion loss, selectivity can be increased substantially.



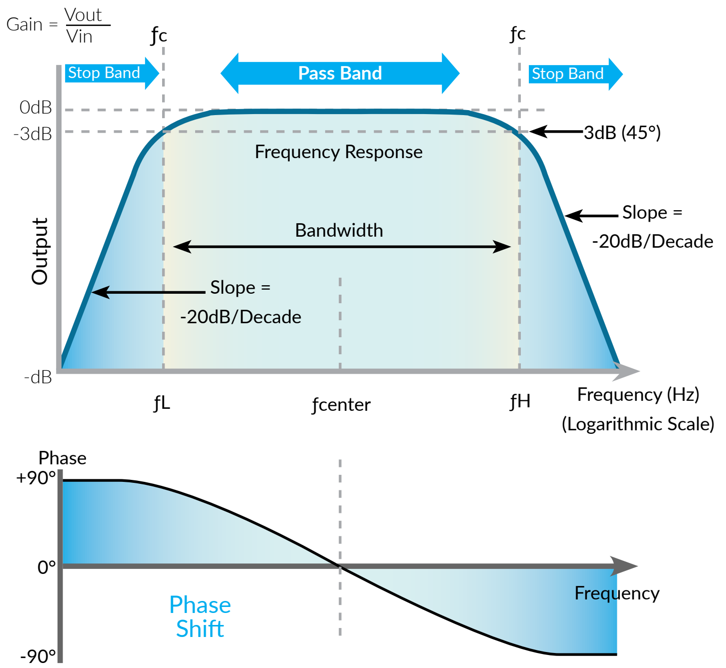
5.13: The effect of bandpass filter on multiple frequencies

The bandpass duplexer

It is the combination of two or more of these bandpass cavities—interconnected in a duplex configuration—that makes a *bandpass duplexer* work. One or more of the cavities are placed in the transmitter part of the duplexer, tuned to allow only the narrow band of transmitting frequencies to pass freely. Similarly, those cavities in the receiving part of the duplexer are tuned to the narrow band of receiving frequencies (figure 5.14).

The transmitter's output signal is filtered through the transmitter bandpass cavities of the duplexer on its way to the antenna, with the desired frequencies experiencing very little loss. At the same time, undesired frequencies are attenuated significantly, reducing the transmitter noise that could otherwise interfere with the signal.

As an added bonus, this reduced transmitter noise not only improves the signal to our own receivers, but those operating on different frequencies as well. By limiting errant frequencies, we reduce the likelihood of receiver desensitization for other users on entirely different channels.



5.14: The effect of bandpass filter on multiple frequencies

Bandpass duplexer
A duplexer that uses multiple bandpass cavities to separate transmitter and receiver signals, allowing for simultaneous two-way communications.

Similarly, the bandpass cavities on the receiver part of the duplexer (again, usually two or more cavities in a duplex configuration) are resonant to receive only assigned frequencies. As with the transmitter's bandpass cavities, there is a modest loss of power in the process of receiving, but unwanted frequencies are attenuated to negligible levels.

The net effect is that off-frequency signals are virtually invisible to the receiver, protecting it from desensitization—not only from its own corresponding transmitter, but from others operating on completely different frequencies.

Isolating the best solution

Modern two-way communications networks must contend with the interfering effects of both receiver desensitization and transmitter noise. While a two-antenna solution is one way to address these factors, most practical applications must contend with space, cost and antenna availability limits. In most cases, a bandpass duplexer provides the requisite isolation between transmitter and receiver, even when operating on the same antenna.

With the isolating properties afforded by a bandpass duplexer, both transmitter and receiver can operate efficiently while reducing transmitter noise and receiver desensitization. The result is a compact, efficient and reliable communications network that easily accommodates two-way communication of voice and data.

Behind every simple call or text on millions of mobile devices at any given moment is a world of complex science and technology at work—and now you have a better understanding of the important role that transmission and receiving isolation systems play in RF communications.

Chapter 5 summary

Duplex RF communications:

- Allow simultaneous two-way signal traffic
- Inherently vulnerable to interference and require isolation to work efficiently

Sources of interference:

- Receiver desensitization
- Transmitter noise

Isolation:

- Techniques that prevent both kinds of interference
- Measured in dB; the higher the dB loss, or attenuation, the clearer the signal

Antenna solutions:

- Polarization separation
- Horizontal separation
- Vertical separation
- Addition of duplexer

Duplexer choices:

- Bandpass duplexer
- Band-reject duplexer

Chapter 6

The many ways to connect:
RF transmission lines

Look around your home and office and you'll see wires, cords and cables everywhere.
In your office, network cables connect your computer to the outside world. In your living room, coaxial cables bring in premium programming and high-definition video cables feed it to your flat-screen TV. In any room of the house, you may have a reliable land-line telephone that can reach out to virtually any person on the planet, all through a slender phone line of twisted copper.

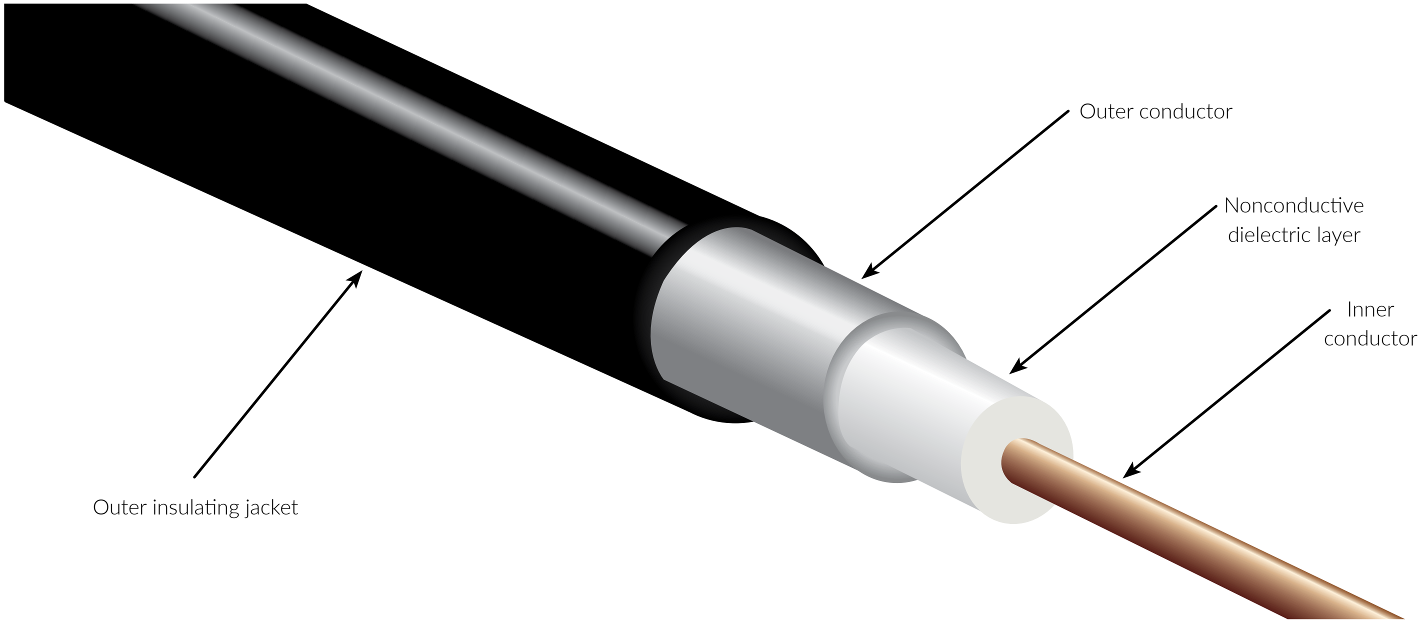
Indoors and out, these connections manage the flow of information that drives our daily lives. **CommScope** is dedicated to the continuous improvement of cable technologies that have an impact on every life, every day.

Different cables are made for an amazing variety of uses, but they all have one thing in common: *they transmit power and patterns from a transmitting source to a receiving destination*. In RF applications, these cables are the hard links that connect antennas to base stations.
They are collectively known as transmission lines.

Transmission line
In RF applications, the physical medium that conducts RF power from one point to another, usually between a base station and an antenna.

Long ago, *transmission lines* were primarily used for the movement of electrical energy. Multi-conductor transmission lines could efficiently connect a power source, like a generator or battery, to a device that would consume that energy. This kind of configuration is common even today. You create a small-scale version of it every time you use an extension cord to connect an outlet to an appliance.

As telephone technology emerged, the limitations of this technique soon became apparent. When passing multiple circuits along a single transmission line, the signals proved highly vulnerable to external interference. To address this problem, Bell Telephone Laboratories developed a new type of cable in the 1930s. It was a shielded cable consisting of an inner wire surrounded by non-conductive material called a dielectric. This nonconductive material was then surrounded by an outer, sleeve-shaped conductor, and the whole assembly was finally encased in an insulating cover. If this design sounds familiar, it's because you've seen it before. This was the first coaxial cable, essentially the same design used today for data transmission (figure 6.1).



6.1: The basic construction of a coaxial cable

In RF applications, *coaxial cable* is used as a transmission line for radio frequencies that only penetrate the outer layer of a solid conductor, a transfer known as the "skin effect." The benefit of this arrangement is that it allows the outer surface of the outer conductor to be grounded.

Signals pass along a coaxial cable by riding the outer surface of the interior conductor and the inner surface of the outer conductor with a nonconductive dielectric layer between them. As a result, the only escape points for the energy carried on the line are at either end—exactly where they're needed for clear transmission.

Coaxial cable
A transmission line built to prevent interference while carrying multiple signals. It consists of an inner core conductor and an outer sleeve conductor, separated by a nonconductive dielectric layer.

Coaxial cable types

Modern coaxial cables used in RF transmission can be grouped into three main categories: solid dielectric, air dielectric and foam dielectric. The construction of each category makes each of them suited to particular uses.

Advantages:	**Disadvantages:**
Flexible Easy to install Inexpensive No pressurization required	High signal loss Prone to deterioration RF signal leakage through outer conductor
Low signal loss High power and frequency capacity Long operational life	High initial costs Pressurization logistics Vulnerability to moisture
Reduced power loss No pressurization required Moderately priced Long operational life Enhanced crush resistance	Slightly more loss than air dielectric More expensive than solid dielectric

Solid dielectric cables employ a flexible inner conductor (stranded or woven, as opposed to a solid wire), covered by solid extruded polyethylene insulation. The outer conductor is braided, and multiple layers can be stacked with shielding foil between them. The outer insulation is a polyethylene jacket.

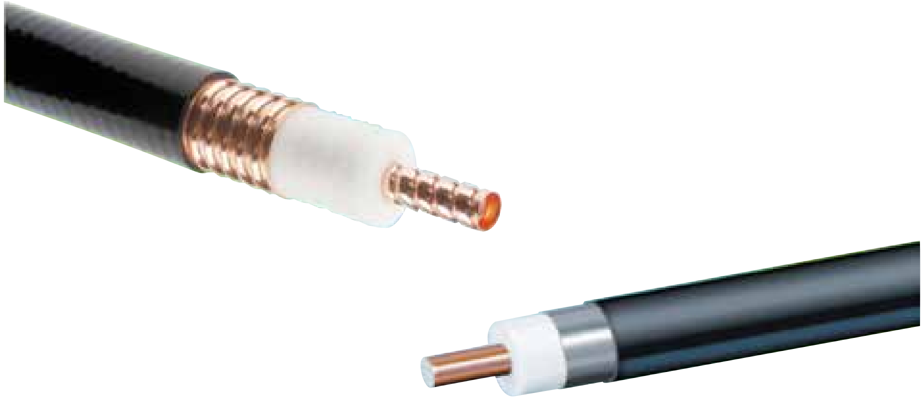
Air dielectric cables are similar to the solid variety except that they employ open space as the inner nonconductive layer. This cavity is supported with small insulating spacers that maintain the open channel and are pressurized to keep out moisture.

Foam dielectric cables employ a solid, as opposed to stranded, copper wire core. The outer conductor is generally smooth aluminum, corrugated aluminum or corrugated copper. The inner nonconductive layer is made of polymer foam, which combines several key advantages from both solid and air dielectric cable varieties. Its power loss and cost characteristics lay between the two other options, but foam also offers practical advantages that make it the preferred choice in many modern two-way RF applications.

The mechanical elements of coaxial cable

Several material choices are available for both the conductive and nonconductive elements of coaxial cable. The specific needs of a particular use determine which combination is most efficient and affordable. Below, you can see two examples of the many varieties available (figure 6.2). Note how they feature different conductive components, but both have the same solid dielectric insulator and outer jacket.

Signal energy is carried along the inner and outer conductor. You will notice that, in both cases, the surface area of the outer conductor is much greater than that of the inner conductor. Therefore, the conductive properties of the inner conductor must be as efficient as possible. That's why highly conductive copper is almost universally preferred.



6.2: Corrugated copper (left) and smooth-wall aluminum (right) coaxial cables

Braided copper is the most commonly used outer conductor on solid dielectric cables. Copper is again chosen for its exceptional conductivity, and it is used in a braided form to improve its flexibility. Solid copper or aluminum material, either corrugated or smooth-walled, is most often used for foam or air dielectric cables. The choice between aluminum and copper often comes down to cost. While aluminum is less expensive than copper, it also has lower conductivity.

In RF transmission lines, the preferred dielectric material is polyethylene due to its low loss characteristics and long life span. This material can be used in either solid or foam dielectric constructions, or as the spacers in an air dielectric design. For high-power applications, Teflon is substituted for its high melting temperature due to the higher operational temperatures. Teflon is more expensive, so there are various other materials with costs and temperature resistances between those of polyethylene and Teflon.

Electrical properties of coaxial cable

Signal loss, or *attenuation*, is a significant consideration in the design of a cable. The loss occurs in three ways:

1. **Conductor loss** is direct function of the conductive properties of the cable's materials.
2. **RF leakage** is a measure of the effectiveness of a cable's shielding.
3. **Insulation** loss is a fixed degree of attenuation inherent in the material of the cable's dielectric layer.

Attenuation is measured in decibels; in the specific case of transmission lines, attenuation is expressed in either decibels per 100 feet of cable length or decibels per 100 meters of cable length.

How well these losses are managed depends on such factors as the size and length of the cable, the conductivity of the materials used in the cable, the frequencies traveling along the cable and the effectiveness of its shielding. There are general physical rules governing how these factors impact attenuation, such as:

Cable size. As a rule, a cable's conductor loss will decrease as its size increases. This is due to a larger cable's broader cross-section and its corresponding increase in conductive area.

Cable design. Solid outer conductors allow less RF leakage than braided ones, though at the expense of flexibility.

Dielectric material choice. By choosing any particular dielectric material, you can anticipate a predictable level of insulation loss. As explained earlier, air dielectric offers the lowest insulation loss, while solid dielectric comes with the highest loss.

Assigned frequency. All three types of attenuation directly increase as a function of the frequency of the cable's signal. The higher the frequency and the shorter the wavelength, the greater the loss in any given cable.

This complex balancing act of performance, ease-of-handling and cost means no single transmission line design is ideal for all, or even most, circumstances. Each design is an exercise in compromise between these factors.

Attenuation
Measured in decibels (dB), this is the loss of power experienced by an RF signal as it moves from one point to another. Transmission line attenuation is expressed in either decibels per 100 feet (dB/100 feet) of cable length, or decibels per 100 meters (dB/100m) of cable length.

Ohm
The unit of electrical resistance. In terms of RF transmission lines, ohms refer to the inherent, or characteristic, loss over a length of cable.

Characteristic impedance

Characteristic impedance, commonly called cable impedance, is a measurement of the electrical resistance of an RF transmission line as measured in *ohms*. The figure is derived by a complex formula involving the ratio between the cable's two conductors. As a general rule the industry standard impedance for RF cable is usually 50 ohms (though some applications require 75 ohms).

This expected degree of impedance can be affected by imperfections or damage in the cable itself. A deep dent in the outer wall of a coaxial cable can cause its impedance to vary from its standard level. This disruption is called a discontinuity, or a change in the distance between the inner and outer conductors, as you might see from a squashed cable. The signal refelects within the cable, creating the same loss of performance as a mismatch between cable and antenna (chapter 3).

This is one reason that a cable's flexibility and crush resistance are such crucial factors. Damage during installation is a frequent source of discontinuity and can be expensive and time-consuming to remedy.

Velocity of propagation

Simply stated, the velocity of propagation within a coaxial cable is the speed at which a signal can travel along that cable. Velocity is governed by the amount and type of dielectric used, and is expressed as a percentage of the speed of light. It can range from 67 percent for solid dielectric cables up to 92 percent for air dielectric cables. However, since the speed of light is more than 670 million miles per hour, velocity is rarely a concern in itself, though there are exceptions. For example, velocity becomes significant in cases where phasing is required (chapter 3).

Power handling capability

The amount of power that a particular transmission line can handle is dictated by two measurements of temperature: the ambient temperature (the temperature of the air surrounding the cable) and the temperature of the cable itself under ordinary operation.

As we've seen, power loss is inherent in any cable design, and is dependent upon the kind of dielectric used in the line. This lost RF power translates to heat, so the greater the attenuation within a cable, the more heat it will generate from that lost energy. Likewise, the greater the frequency passing along any given cable, the more heat it will generate as a function of loss.

Heat resistance is a critical factor in cable design. For instance, foam dielectrics begin to soften near 180 degrees Fahrenheit, so an engineer choosing the right transmission line will need to be certain that the combined internal and ambient temperatures won't exceed 180 degrees. If the cable exceeds its limit, the softened dielectric will allow the inner conductor to shift, creating a discontinuity. If it should contact the outer conductor, the result would be a shorted cable. To help engineers make the right choice and prevent such failures, cable manufacturers like **CommScope** rate each type of cable for certain power levels at certain ambient temperatures.

RF leakage

As its name suggests, RF leakage is a function of the physical ways an RF signal can "leak" out of a transmission line. In the case of a cable with a braided outer conductor, there are countless tiny openings in the cable. As with a leaky garden hose, the more power or pressure you apply, the more significantly those leaks affect performance.

In addition to attenuation, RF leakage causes another challenge when several high-power braided coaxial cables are arrayed in close proximity to one another. The leakage can cause interference between the cables at their endpoints, such as when they connect to antennas, multi-couplers, duplexers and so forth. Faulty connections can make this problem worse.

As with power handling, RF leakage is included in a cable's specifications to help engineers choose the best option for any particular configuration, especially in circumstances where many cables terminate close together.

Environmental factors

The climate and setting of a cable installation dictates what kind of cable should be used. Considerations include:

- Sunlight UV exposure
- Humidity and moisture
- Temperature extremes

Cable life expectancy

The expected useful life span of a coaxial transmission line depends largely upon *environmental factors*. Since engineers have little control over these factors, they must compensate by choosing the right design with the right materials to assure the longest possible life span.

The composition of the cable's outer jacket is one of the more obvious considerations. Most flexible and semi-flexible coaxial line jackets use polyethylene, polypropylene, or polyvinyl chloride (PVC). All three options are vulnerable to long-term sun exposure, so manufacturers incorporate carbon black into the resin to improve the jacket's resistance to aging under ultraviolet light, which can extend their operational lives up to 20 years of service. This improvement is why so much coaxial cable you see in household use is black.

Moisture and humidity are important factors as well. While water can infiltrate through tiny nicks, cuts or age cracks in the cable, the single most common form of moisture infiltration is through improperly sealed connectors on the ends of the cable. Even humid air present inside the connector can condense as temperatures fall, resulting in liquid water that wicks deeper into the cable along the outer conductor's braid. This can potentially corrupt the entire cable and short the inner and outer conductors, particularly in the connectors themselves. The result is increased signal reflections within the cable and degraded passive modulation performance.

Connectors

As the number of modern RF applications has grown, the technology used to connect a cable to its terminus has evolved. The simple designs created in the 1940s for military uses have diversified and improved into a variety of types such as these (figures 6.3 through 6.8).

UHF connectors are the oldest and most popular type still in use for two-way communications. They are rugged, reliable and easy to install, which is why they are the preferred choice for applications with frequencies up to 300 MHz.

BNC connectors are small, quick-disconnect versions with a bayonet-style locking coupling. These are often used on narrow cables connecting equipment.

TNC connectors are similar to BNC connectors, but include threaded connections that keep them secure in environments where vibration is a concern.

Type-N connectors are an industry favorite for RF communications with frequencies above 300 MHz, where UHF connectors are not suitable. Type-N connectors may be rated to perform at 10 GHz or even higher.

EIA flanges are used primarily on pressurized air dielectric cables operating above 450 MHz. These connectors offer the standard 50 ohms of impedance and typically offer higher voltage characteristics than Type-N connectors.

DIN (Deutsche Industrie Normenausschuss) connectors are available in several sizes and have come to dominate the RF communication industry as a whole. They have a larger cross-section than Type-N connectors, and better withstand the rigors of field installation.

For exceptionally congested installations with multiple service carriers operating in the 700, 800, 900 and 1900 MHz bands, silver-plated Type-N or DIN connectors are required.

6.3: DIN coax connector

6.4: BNC coax connector

6.5: TNC coax connector

6.6: Type N connector

6.7: EIA flange coax connector

6.8: UHF coax connector

Voltage standing wave ratio (VSWR)
A key measurement of cable performance and signal quality. It quantifies the amount of signal reflected backward along a cable to its source. Theoretically, perfect operation yields a VSWR value of 1.0, or "unity," meaning zero reflections.

Installation step 1: cable choice

As discussed above, choosing an appropriate cable depends on knowing:

- Which frequencies it will carry
- How much loss is tolerable
- Where it will be installed
- What kind of budget limits exist

In most cases, there will be more than one acceptable cable solution for any one of these four criteria, but the key is to get the greatest possible benefit against all four. For instance, if we look at cost as the primary driver, we see that smaller-diameter cables cost less to purchase and install, but will need more upkeep and eventual replacement. We may also consider a less expensive option with a higher rate of loss, intending to compensate for that loss through greater RF power generation on one end of the cable or increased antenna gain on the other.

Installation step 2: field testing

Once you have selected and installed the cable that best performs to your application's priorities, the process of fine-tuning that performance can begin. There are three tests you would likely perform: inner and outer conductor continuity, shorts between conductors, and a *voltage standing wave ratio (VSWR)* test.

The first two tests are simple and direct measurements of impedance in the cable, performed with an ohmmeter. Any physical disruption of the cable's integrity would be revealed in a non-standard level of impedance, and you could begin inspecting the cable for the source of the problem.

The third option, the VSWR test, is an indirect but ultimately more revealing measurement of overall line performance. Basically, the VSWR test measures the amount of signal reflection taking place within the cable. Measuring both forward and reflected power with a wattmeter, you can compare the values against the cable manufacturer's conversion chart for that particular type of cable. If everything is functioning correctly, the observed amount of reflected energy should fall within expected limits. Poorly made connections or connections with mismatched impedance will quickly become obvious. This process is explained in more detail early in chapter three.

Installation step 3: troubleshooting

Reduced RF communication performance can be rooted in any number of problems, occurring in any component in the system. When the antenna and transmitter have been ruled out as potential trouble spots, it's time to examine the transmission lines because a lot of things can go wrong with cables.

Here are just a few things that can cause system performance to drop suddenly:

Weather. A good place to start is to visit the site itself and speak to those familiar with recent weather trends. A bad storm, lightning, hail or high winds can damage cables and loosen connectors.

Local phenomena. In addition to weather, other local events can impact performance. Explosions from nearby mining operations, small earthquakes, even a stray bullet from a hunter's gun have been identified as culprits.

Water infiltration. As discussed earlier, water is perhaps a cable's greatest enemy. Checking connectors for signs of moisture, double-checking their seals, and examining the cable itself for any new damage will help confirm or rule out water as a cause.

In any event, once the damage has been identified, that section of cable cannot be taped or otherwise repaired. It must be replaced. Long-term system performance degradation can be just as serious, and is often caused by cable aging. While metal-sheath cables are almost impervious to aging when properly installed, inferior cables can age and crack with extended exposure to the sun's UV rays and extreme temperatures.

Localizing the problem

If your VSWR measurements reveal a high level of reflection—say, 20 percent above the level indicated by the manufacturer's table—then, most likely, your cable is experiencing an open, a short or a partial short somewhere along its length or in a connector. To confirm this, you could perform the following tests:

1. Open the top of the cable and short the inner and outer conductors (the cable ground should be removed for this). Measure impedance between the conductors with an ohmmeter. An intact cable will show low impedance between the two, while high impedance will reveal damage to the outer conductor. This kind of damage is hard to locate. If economically feasible, replacement may be the best option.

2. Remove the short between the conductors and test impedance again. In this instance, an intact cable will show high impedance, while low impedance may indicate damage to the inner conductor that creates a short somewhere within the cable. The damage required to cause this kind of fault often leaves more obvious traces on the outer jacket and is easier to identify.

3. Examine the connectors themselves. Type-N connectors are particularly vulnerable to misalignment and pin breakage, which can result in a short. Also, as the primary source for any potential water infiltration, it's a good idea to examine any type of connector for signs of moisture. For best results, check connectors during cool weather or at night, where any trapped vapor will have condensed into more visible droplets.

4. Practice good preventative maintenance. Proper installations reduce the need for ongoing maintenance, but vigilance is always to your benefit. Any time an installation is realigned or painted, it's smart to inspect the cables and connectors. Identifying small problems before they become big problems can save a great deal of time and money and minimize lost performance.

In summary, a solid understanding of the construction of cables helps you understand their best applications, where they may be vulnerable, and where to look when a fault is suspected.

Transmission lines connect the world

While so much of modern RF communication is comprised of radio energy radiated through the air, the critical links on either end depend on the right kind of transmission line cable and the right connectors between base station and antenna.

As a physical link, these cables must be able to flex where they're needed, withstand the punishing elements, and faithfully carry the frequencies that eventually reach you as your internet connection, land-line call, or mobile phone call virtually anywhere in the world.

You live among small-scale examples of the same technology at home. From the USB cord on your computer mouse to the century-old design of your telephone's wall cord, each cable is designed to carry specific frequencies over specific lengths, each one for a unique purpose. As a leading provider of coaxial and other transmission line products for networks all over the world, **CommScope** is at the forefront of the race to develop innovative solutions that will address the future of technology tomorrow.

Chapter 6 summary

RF transmission lines:

- The bridge between base station and antenna
- Adapted from designs once used to carry simple electricity

Coaxial cable:

- Characterized by insulated inner and outer conductors
- Solid dielectric
- Air dielectric
- Foam dielectric

Mechanics and materials:

- Copper used for inner conductor
- Copper or aluminum used for outer conductor
- Polyethylene used for dielectric insulation
- Various connectors for different applications

Design considerations:

- Cable impedance
- Velocity of propagation
- Power-handling capability
- Heat and frequency limits

Measuring performance:

- Conductor loss
- RF leakage
- Insulation loss
- VSWR testing and fault detection

Chapter 7

Making every connection count:
Passive intermodulation (PIM) fundamentals

It's a fact of life for electronic devices: when something isn't working correctly, we check the connections. From the most complex cellular transmission system to the simplest toaster, junctions between cables and components are the most likely place for problems to occur.

But beyond the obvious culprits like poor connections, water infiltration or mechanical issues, a communications system's connections can also play host to other problems. One example is *passive intermodulation* (PIM), an inherent product of the system's frequencies and their associated harmonics. PIM can create undesirable sideband frequencies that interfere with the system's assigned frequencies. It takes a knowledgeable partner like **CommScope** to choose the right components and assist in the design and installation of a communications system.

Passive intermodulation (PIM)
A potential side effect of having more than one high-powered signal operating on a passive device such as a cable or antenna. PIM occurs at non-linear points in a system such as junctions, connections or interfaces between dissimilar metal conductors, creating interfering frequencies that can decrease efficiency. The higher the signal amplitude, or power, the greater the effect.

Intermodulation explained

The growing demand for wireless services has increased the complexity of system design and the resources to support that demand. As a result, there are more RF components, configurations and spectrums utilized in the RF path. Included in these additional components are passive devices that can contribute to PIM. With a good understanding of these PIM contributors, we can proactively address PIM and its impact on the system noise floor.

Because PIM will act as a component of the overall noise floor, we will first discuss the components of system noise and how noise impacts network performance. The system uplink noise floor is dynamic and affected by PIM and other factors. It is also driven by the number of active users. For every new user added to the site, additional noise is added to the network, causing a "noise rise". As new users raise the noise floor, each user must deliver a higher power transmit signal to overcome the increased noise. This means the user must be closer to the receiving cell tower. Consequently, the cell coverage area is reduced.

There is a theoretical limit to "noise rise" and a consequent corresponding limit to the number of users that can be added. This theoretical maximum number of users is referred to as the "pole capacity" of the network.

Uplink pole capacity is proportional to the system signal-to-interference/noise ratio (SIR) and several other variables and, for WCDMA networks, can be estimated using the following widely accepted formula:

$$Np=(W / R)/((1+ f)*AF*10^{(EbNo/10)})$$

where

Np = Pole capacity

W = Spreading bandwidth

R = Users' radio bit-rate

f = Ratio of other-cell interference to in-cell interference

AF = Activity factor

Eb/No = Ratio of energy per information bit to power spectral density of noise + interference

Notes:

1) Basically, Eb/No represents the amount of gain that must be provided above noise and interference for acceptable system performance

2) Eb/No can be expressed as Eb/No = Processing Gain + SIR, where SIR is the Signal-to-Interference/Noise ratio

3) For 3G voice at a CS12.2K data rate, the Eb/No requirement is typically 5 dB

An example pole capacity calculation estimating the uplink capacity for a WCDMA cell site is shown as follows:

Np = Pole capacity

W = 3.84 Mhz (value for 3G UMTS)

R = 12,200 bits/second (value for CS12.2K for 3G UMTS voice)

f = 65% (typical network value)

AF = 50% (typical network value)

Eb/No = 5 dB (typical value for 3G UMTS)

Np = (3840000 Mhz / 12200 bit/s) / ((1+0.65) * 0.50 * 10^(5 / 10))

Np = 20.6 users maximum

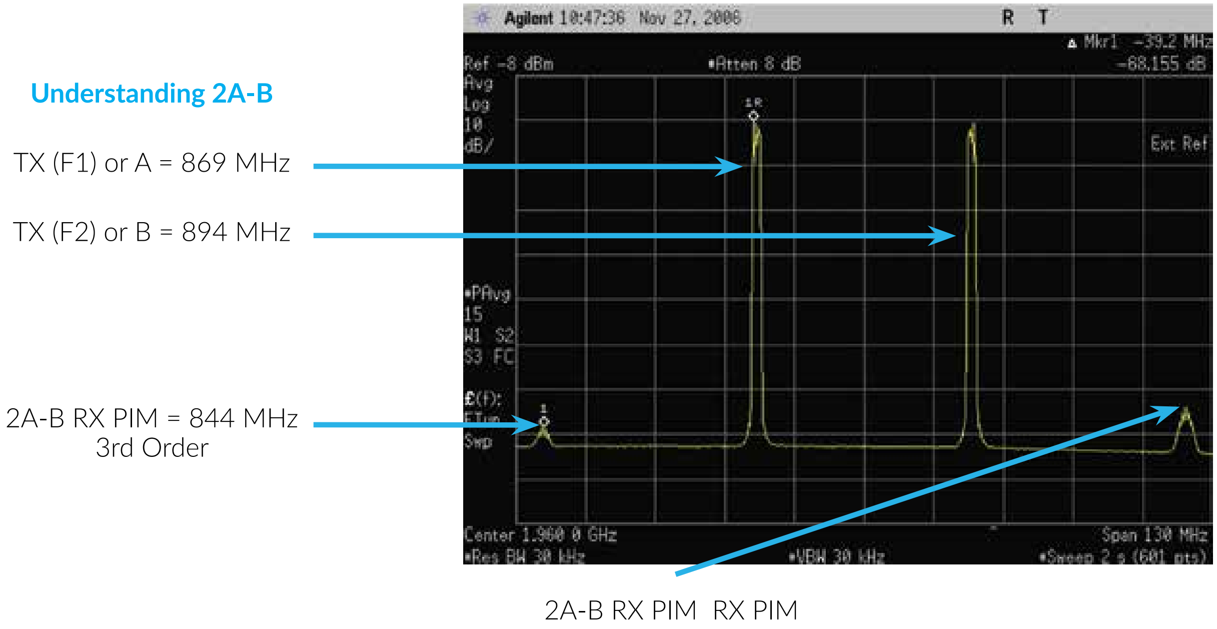
We can see from the above pole capacity equations that increases in the system noise floor can degrade system performance, increase system power consumption and reduce cell coverage area. Because PIM, when not mitigated, can be a significant contributor to noise, it is clear now the serious impact it can have on wireless network performance.

Now that we have developed an understanding of the system level impact of PIM, we will describe specifically how PIM is generated and how it can be mitigated.

Generally speaking, intermodulation is the result of two or more frequencies (often, a duplexed system's receiving and transmitting frequencies) interacting with one another according to certain mathematical relationships related to their specific frequencies. The effect creates errant signals that contribute to noise and interfere with the system's operation.

Passive intermodulation is a particular kind of intermodulation that takes place in the passive parts of a system—such as cables and antennas—often at connections that create nonlinearity in the system.

As the complexity of communications systems has increased, so has the potential for PIM, making it a top priority for service providers to manage its effects. In a cellular base station, for example, a transmitting frequency can create PIM interference in its own receiving frequency, or vice versa. Where PIM occurs depends on the separation of the two main frequencies, as shown in the chart below (figure 7.1).



7.1: Calculating where PIM will occur, based on two example frequencies, A and B; in this example, PIM occurs at 2A-B (a common 3rd order product) and again at 2B-A

Calculating potential PIM

In this example, transmission frequency A (869 MHz) and transmission frequency B (894 MHz) create potential PIM problems at 2A-B (844 MHz) and at 2B-A (919 MHz). This means we must expect troublesome interference if our reception frequencies include 844 MHz or 919 Mhz.

Nonlinearity

A location within an electrical circuit where voltage does not remain consistently proportional to power. This effect is caused by imperfect connections between components and cables.

Managing PIM

Since we don't always have the freedom to select frequencies that avoid PIM issues, we need to look at other methods of reducing its influence in our communications system. Reducing PIM levels starts with reducing nonlinearity in the circuit.

Nonlinearity in a passive RF circuit typically results from current rectification at the conductor joints and mechanical junctions. Resolving nonlinearity generally means improving connections throughout the RF path of the system. This means addressing problems such as:

- Improper connector attachment
- Poorly torqued connections with incorrect contact pressure
- Contamination or corrosion of conducting surfaces
- Inadequate plating on rust-prone ferromagnetic components
- Poor connections due to cold solder joints

The most common and visible contributors to high PIM levels in the system are associated with the mechanical and physical integrity of the connections in the RF path. Therefore, those who deal directly with the RF components in the field, such as installers, service technicians and test engineers are integral in the battle against PIM. They will require training in proper field installation, proper use of PIM test equipment and a fundamental understanding of PIM.

In order to manage PIM, we also need to understand the environment in which we are performing the PIM testing. For a manufacturer, it is now common for PIM to be tested in a controlled RF environment such as an anechoic chamber. This is done to ensure the device under test has an isolated and "quiet" RF environment to confirm the PIM performance as it relates to the published manufacturer specification.

Field testing presents an entirely different set of challenges if PIM performance testing is required. This is not an isolated or "quiet" RF environment. This noisy RF environment can negatively impact PIM or provide false PIM levels that are a direct result of the environment. In other words, you may obtain PIM levels in your testing that are not reflective of the actual device under test, but rather the RF environment in which it is tested. Shown on the next page are some examples of base station antenna testing where the environment impacted the PIM measured in the field.

Although conditions such as external RF signals or the test environment may not be controlled, the selected components, installation practices and testing are within our control. Education and awareness are the first steps in managing the difficulties associated with field PIM testing.

System PIM calculators

Reducing PIM in the RF path is important and challenging. CommScope provides several PIM system calculators to support your RF path analysis.

Researching, testing and installing

The severity of PIM is directly related to signal amplitude, or power. That's why PIM performance of different RF components specify power levels along with their other properties. Typically, this figure is calculated by applying two signals of close frequencies at 20 watts (+43 dBm), the industry standard for PIM testing. This standard helps assure that comparisons between different products yield meaningful answers.

Understanding the PIM properties of components like cables, connectors, combiners, filters, tower-mounted amplifiers and antennas allows you to design a system with minimal exposure to potential PIM issues. It's a meticulous process, but it's essential to preventing potentially crippling PIM problems later on:

- Choose a knowledgeable provider that has demonstrated experience in the PIM specification of their products—one who can help you make the right component choices. **CommScope** makes this expertise freely available to our customers.
- Test your component performance against PIM specifications to assure trouble-free operation later on.
- Use trained installers certified in preparation and installation techniques. Since they will be managing connections, and connections are the source of PIM, their skill is your best guarantee against problems.

By following these recommendations, you can count on an RF system that will operate efficiently, virtually free of troublesome PIM effects.

PIM: best addressed at the planning stage

In engineering, connections are perennial trouble spots. Each connection, junction and interface is an opportunity for something to go wrong, including passive intermodulation (PIM).

The only way to design the system to mitigate PIM is to study and test the PIM specifications of the components comprising that system, which is why partnership with **CommScope** is so vital. We provide the experience and insight to spot potential trouble early in the process. Visit the PIM-dedicated portal of our website, to learn how we can assist you with awareness, prevention, identification, resolution and support.

Chapter 7 summary

Passive intermodulation (PIM):

- Caused by interactions between multiple frequencies and their harmonics
- Can cause transmission or receiver frequencies to interfere with each other
- Occurs as a byproduct of nonlinearity in a circuit, such as at a connection
- A critical consideration in the selection of components and installation of those components in an RF system

Chapter 8

The infrastructure behind the connection: Microwave backhaul

Imagine two kids, each standing in their own backyards, talking to each other on soup cans connected by a string. This is the simplest of connections, nothing more than two users on a direct, point-to-point, dedicated line. This same simplicity applies if we replace the cans with walkie-talkies—the communications system is still reliant on just two points of contact.

Once the system becomes more complex, like modern distributed communications networks with millions of users, these simple connections are no longer practical or possible. A centralized processing point is needed to route many conversations simultaneously just to make the correct phone ring when you dial its number.

This centralized processing is called *backhaul* and it's the infrastructure behind the connection where you'll find many **CommScope** solutions.

Backhaul
The process of connecting two ends of a transmission through a central routing point.

To imagine backhaul in action, consider the classic image of an early 20th-century telephone operator, manually connecting calls at a switchboard. As more and more people call at the same time, the task soon grows very complex—eventually, too complex for humans to perform.

Today's modern cell phone networks require much more complex connectivity—collectively called backhaul—than even the fastest human operator could provide. The process of routing network traffic for a cell phone call requires many steps to complete, and looks something like this:

1. Mary makes a call to John on her cell phone from her office
2. Mary's outbound call is picked up by the nearest cell tower
3. The tower routes Mary's call to the area's regional network
4. The regional network sends Mary's call to the national network
5. The national network routes Mary's call to Bill's regional network
6. The regional network broadcasts Mary's call from the nearest cell tower
7. Bill's cell phone rings, he answers and the call connects

Backhaul is the process of routing Mary's cell call—and all network traffic—up to, then down from the core processing backbone between the cell tower nearest to Mary and the one nearest to Bill. While backhaul can be achieved over a number of different materials, such as twisted-pair copper cable, fiber optics or coaxial cable, microwave backhaul offers a time- and cost-efficient backhaul link, ideally suited to cell phone networks that move calls and data across the country and across the world millions of times every day.

Microwaves and the electromagnetic spectrum

The electromagnetic spectrum includes an incredible variety of radiation types, all expressed in Hertz (Hz), a measurement of a particular radiation's frequency. Most frequencies used in electronics are expressed in thousands of Hertz, or kilohertz (KHz); millions of Hertz, or megahertz (MHz); billions of Hertz, gigahertz (GHz) or even trillions of Hertz, terahertz (THz). Some of the more familiar types are listed below (table 8.1).

Frequency	Wavelength	Application
50–60Hz	6000–5000km	AC electricity transmission
3–30kHz	100–10km	Sub-marine communication
30–300kHz	10–1km	Long-wave radio broadcast
180–1600kHz	1.7km–188m	AM radio broadcast
1.8–30MHz	167–10m	Shortwave radio
88–108MHz	3.4–2.7m	FM broadcast
300–3000MHz	1–0.1m	UHF point-to-point
700–2700MHz	0.43–0.11m	Mobile base station
0.3–300GHz	1–0.001m	Microwave/Millimeter Backhaul
352, 230, 193THz	1550, 1300, 850nm	Fiber-optic links
420–750THz	714–400nm	Visible light

8.1: Applications associated with different radiation wavelengths within the electromagnetic spectrum

Microwave backhaul frequencies

The International Telecommunications Union (ITU) regulates the microwave spectrum available for backhaul applications. Each band is best suited to particular situations of topography, climate, bandwidth requirements and cost, determined in large part by their typical hop lengths, or the distance each band can travel in open air between points (table 8.2).

You may notice that the table includes several "unlicensed" frequency bands. While most microwave frequencies are regulated to prevent interference during hops, unlicensed frequencies are unregulated, requiring cooperation between operators to prevent interference.

The highest bands, 60 GHz and 80 GHz, possess unique propagation characteristics, as shown in their very small maximum hop length. They serve a special purpose which we will discuss later in this chapter.

Frequency band	Frequencies (GHz)	Typical maximum hop length (km)	Typical minimum hop length (km)
0.9 (unlicensed)	0.902–0.928	100	–
2.4 (unlicensed)	2.4–2.5	100	–
4	3.6–4.2	70	24
5	4.4–5.0	60	16
5 (unlicensed)	5.3, 5.4 & 5.8	50	–
L6	5.925–6.425	50	16
U6	6.425–7.125	50	16
L7	7.1–7.75	50	10
U8	7.75–8.5	50	10
10	10–10.7	20	10
11	10.7–11.7	20	10
13	12.7–13.25	20	6
15	14.4–15.35	20	6
18	17.7–19.7	20	2
23	21.2–23.6	20	2
26	24.25–26.5	20	2
28	27.5–29.5	15	2
32	31.0–33.4	10	1.5
38	37.0–40.0	10	1
42	40.5–43.5	10	1
60 (unlicensed)	57.0–66.0	1	–
80	71–76/81–86/92–95	5	–

8.2: Typical hop lengths for microwave frequency bands

Duplex communications
A transmitter and receiver that work in different time slots or frequency slots on the same device.

Microwave advantages

The microwave band possesses characteristics ideal for radio transmissions, including those from cell phones:

- They help directional antennas make hops from point to point in narrow beams that don't interfere with each other
- The low end of the band (below 11 GHz) propagates over long distances, ideal for long-haul connections to users in remote locations
- The higher end of the band (above 11 GHz) propagates over shorter distances, ideal for short-haul connectivity required in urban locations

In addition to their technical characteristics, microwave links also offer practical and financial advantages over cable solutions, which have made them the preferred choice for modern communications networks:

- Less expensive to establish and operate
- Faster deployment
- Greater bandwidth than twisted-pair copper, critical to high-traffic applications like modern cell phone networks
- Readily scalable to handle more traffic as required
- Very reliable to operate

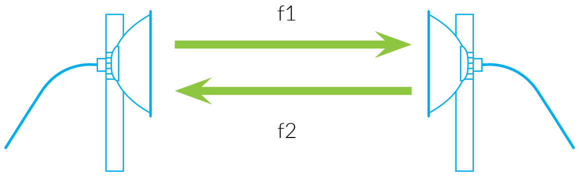
Microwave backhaul in action

Let's revisit the process of making a cell phone call. The user dials the call and the cell phone connects with the nearest cell tower, operating on the network's radio frequencies (within the 700–2700 MHz part of the spectrum). The cell tower hands off the call to a microwave transmitter (typically into one of the bands between 6–40 GHz) which directs it via a directional beam—a hop—to a collection or aggregation center which, in turn, makes the connection to the mobile network's core network. The traffic is then routed across the network to the region closest to the receiver's location, where it will be transmitted again by microwave to the nearest cell tower.

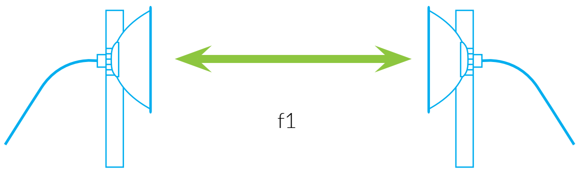
The receiving cell tower station down-converts the microwave signal back to the network's radio frequencies for its final journey to the target cell phone. The process is reversed for traffic moving in the opposite direction.

This two-way microwave backhaul generally uses a frequency-division duplex (FDD) system that allocates frequency channel pairs for simultaneous two-way, or *duplex communication* (figure 8.3).

Another way to achieve duplex communication is via a time-division duplex (TDD), which achieves the same goal by switching the required direction of transmission in a very fast, precise manner (figure 8.4). While a more efficient option, TDD requires very careful timing control and is not the preferred system for microwave use.



8.3: Frequency-division duplex (FDD) system with separate go/return frequencies



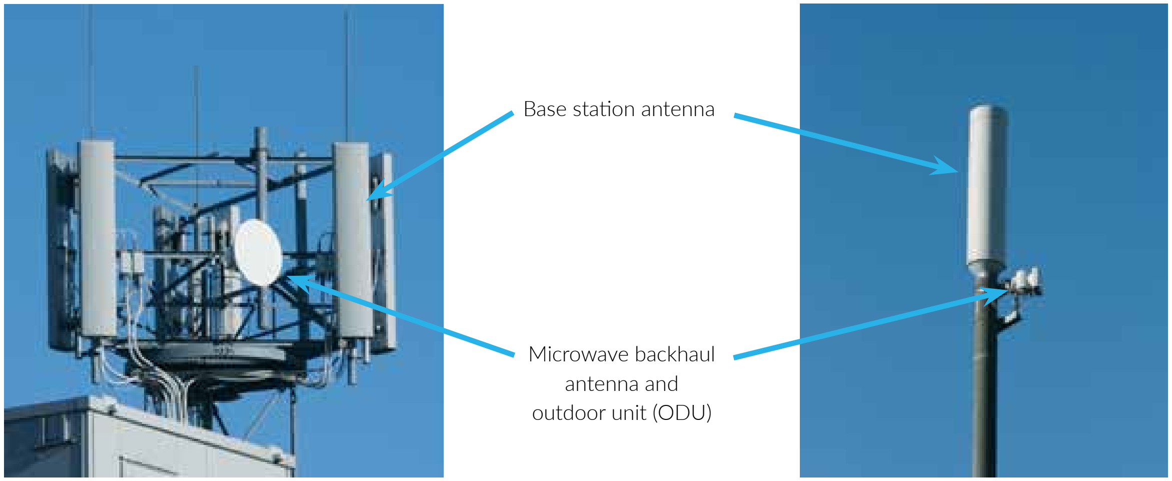
8.4: Time-division duplex (TDD) system using just one go/return frequency

Typical microwave deployments

Hop connections between microwave transmitters and receivers usually require *line-of-sight* (LOS) clearance. LOS means both ends can literally “see” one another without any obstructions in between—including the curvature of the Earth’s surface. For this reason, microwave antennas are often mounted on towers or at the top of high buildings for best LOS clearance.

To maximize the value of these choice locations and to reduce the costs for leasing these locations, microwave backhaul antennas are often mounted adjacent to base station antennas, which also rely on altitude for efficient operation (figure 8.5).

Line of sight (LOS)
The unobstructed space between transmitter and receiver. Longer hops must even account for the curve of the Earth as an obstruction.



8.5: Typical microwave backhaul antenna integrated into a base station antenna location

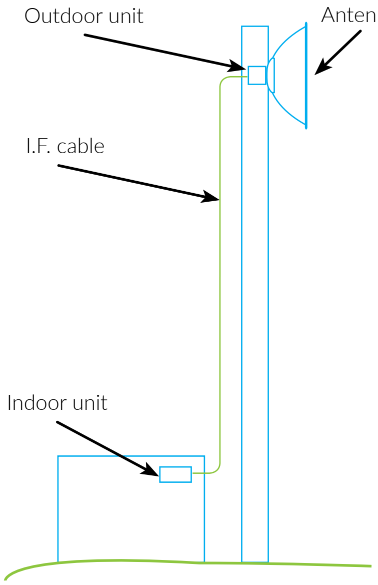
Split-mount radio system
A two-stage connection that lets microwave radios located in an indoor unit (IDU) receive and transmit through an antenna fitted with an outdoor unit (ODU).

Many short-haul installations, typically operating above 11 GHz, use a *split-mount radio system*, which divides the radio into an outdoor unit (ODU) and an indoor unit (IDU). The ODU houses the microwave circuitry, including the go/return microwave signal separating diplexer and the up/down frequency converters. It is mounted in an enclosure adjacent to the antenna, or more frequently integrated into the antenna assembly itself (figure 8.6).

The IDU contains the modulator/demodulator, more commonly known as a modem, and the control circuitry necessary for translating the cell phone traffic into a form suitable for microwave transmission.

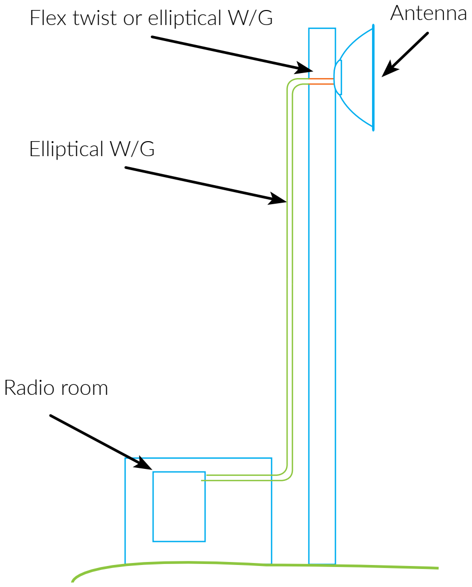
For high-density traffic and long-haul hops, multiple radios are typically housed in a remote radio room adjacent to the base of the tower. Generally, these hops use larger antennas operating at frequencies under 11 GHz (figure 8.7).

Connections between the antenna and the radios are made by coaxial cable, elliptical waveguide or circular waveguide transmission lines, depending on the frequencies involved (figure 8.8). Chapter 6 provides detailed information on transmission lines.



8.6: Typical split-mount microwave radio system showing IDU and ODU

8.7: A typical lower frequency aggregation point

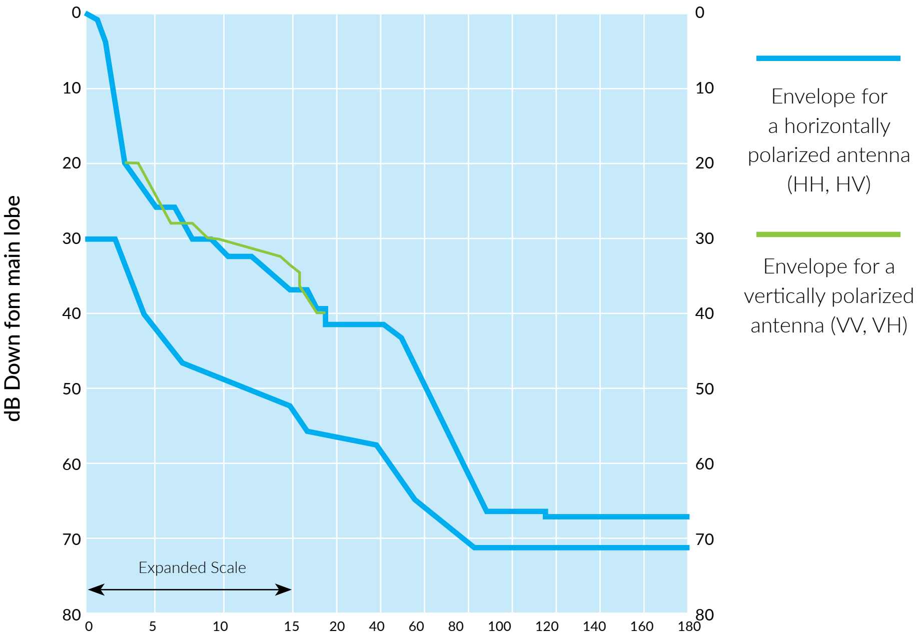


8.8: Connections between remote microwave radios and a microwave antenna

Planning a microwave link

When considering a new microwave backhaul path, it is important to consider potential interference issues during the design process. The planned link must not interfere with adjacent links or other operators in the area. To prevent conflicts and other problems, you must consider:

- Frequency coordination with other links in the vicinity
- Radio and radiation characteristics of the antenna
- Transmission power levels



8.9: A typical radiation pattern envelope (RPE) document

To avoid these issues, industry standard software tools such as iQ-link®XG from **CommScope** can smooth the planning process and assist in regional overview. Antenna manufacturers offer assistance as well, providing planners with the radiation pattern envelope (RPE). An RPE document includes a performance summary and the key specifications related to antenna gain, beam width, cross-polar performance and radiation patterns (figure 8.9).

The chart describes the directional properties of the antenna by mapping it directionality (in dB) against its azimuth angle. As this chart shows, the envelope has a main beam area at zero degrees, corresponding to the electrical axis of the antenna. This is the line-of-sight direction, where the directionality is at its maximum.

Away from the main beam, the directionality quickly decreases. This corresponds to a drop-off in antenna sensitivity, whereby signals transmitted or received away from the on-axis direction reduce rapidly. The link planner uses this information to determine how much of their new proposed link signal will deviate from the intended direction and assess whether this is likely to present problems (e.g., interference, threshold degradation, etc.

Because of their importance in the planning process, RPE documents are strictly regulated. In Europe, the European Telecommunications Standards Institute (ETSI) publishes several classes of envelope standards that all antennas must satisfy. A Class 2 antenna may be permissible in locations where interference is not an issue, but cannot be used where a Class 3 antenna's stricter standards are required. The importance of using Compliant Class 3 or better specification antennas is discussed in further detail in a later section.

Most regions across the globe have adopted ETSI standards with the notable exceptions of Canada, Australia and the United States, which have their own regulatory envelope minimum standards.

Signal polarization
The orientation of a signal's electric field relative to the ground. It may be horizontal or vertical.

Protecting microwave systems from the elements

Like every stage in the chain of communication, backhaul must be reliable and available at all times. Downtime means lost revenues, irritated customers and expensive repairs. In practical terms, downtime is measured as a percentage, or in minutes per year (table 8.10). A detailed explanation of reliability predictions and measurement can be found in chapter 10.

Downtime, minutes per year	Availability
525.6	99.9000%
52.56	99.9900%
26.28	99.9950%
5.256	99.9990%

8.10: Downtime in minutes per year and corresponding availability percentages

This growing need for reliable communications within realistic budget constraints is partly what drives demand for microwave backhaul. However, due to its open exposure to the elements, certain reliability-limiting factors are unavoidable:

- Precipitation and moisture
- High winds
- Temperature variances
- Lightning strikes
- Atmospheric refraction

Fortunately, each challenge to reliability has an available mitigating measure.

Rain and snow

As mentioned earlier, lower-frequency microwave bands propagate very well across long distances, allowing hops of 50 km or more. In fact, the most significant limiting factor is not distance itself, but atmospheric conditions. Rain falling through the signal path reduces signal strength, an attenuating phenomenon known as "fade."

In frequencies above 11 GHz, rain-induced attenuation becomes more pronounced, reducing hop distances accordingly. Rain, and to a lesser extent, snow, can scatter signals in these frequencies. The impact depends on the rate of precipitation, the frequency involved and the signal polarization (the orientation of the signal wave, which may be horizontal or vertical).

Horizontal signals are more adversely affected by rainfall due to the shape of raindrops as they fall, so vertical polarization is the preferred choice for any link-planning.

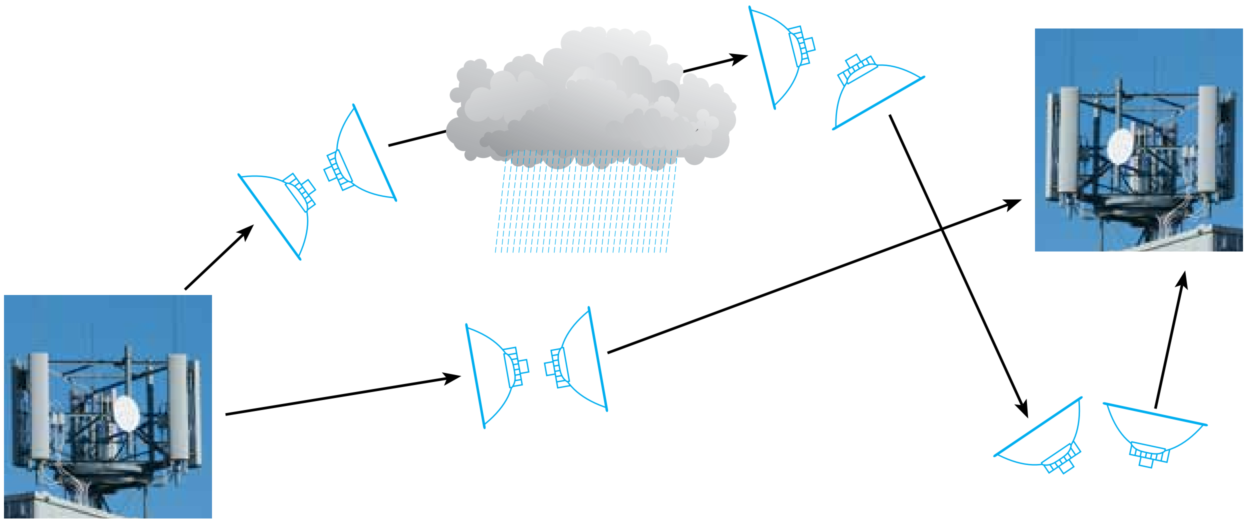
Fortunately, it is possible to mitigate these effects based on the calculations of rain outage models, building a safety margin into the transmission's power levels to compensate for expected loss and assure a reliable hop between stations. Modern microwave radios will even adjust power on the fly when needed, using an automatic transmit power control (ATPC) system.

Precipitation also interferes with polarized transmissions through an effect called polarization rotation, which essentially turns a signal's polarity enough to interfere with other signals. To counter this effect, a cross-polar interference canceller (XPIC) samples signals in both polarities in order to produce a wave that cancels out the interfering, "rotated" part of the signal.

Adaptive modulation

Another technique gaining widespread acceptance in microwave backhaul applications is called adaptive modulation. In addition to compressing, or modulating, network traffic into smaller bandwidths at higher signal levels, adaptive modulation adjusts the amount of modulation in response to any link impediments. The result is that adaptive modulation can dynamically reduce traffic to compensate for the impaired signal level while still maintaining the link, albeit with lower capacity.

Mitigation methods can also be built into link designs themselves. In multiple-hop situations, mesh and ring topologies provide alternative signal paths that bypass problematic hops by rerouting around them. Path selection is dynamic and adapts on the fly to changing conditions (figure 8.11).



8.11: Network topology with dynamic routing paths

Automatic transmission power control (ATPC)
A system that dynamically raises transmission power to overcome the effects of interference.

The Sentinel Performance Advantage:

Microwave antennas with specialized adaptive modulation schemes

Radome
A wind- and water-proofed fabric or plastic cover that protects an antenna from the elements.

Fog

Fog only presents a challenge to the highest microwave bands above 60 GHz. Unlike rain, snow and other precipitation, it presents no real obstacle to lower, more commonly used microwave frequencies.

Temperature

By itself, temperature has little effect on microwave signals. However, if water vapor is present in transmission lines, it can condense there and impede performance when the temperature drops. The effect is similar to the attenuation caused by rain.

The hardware effect

In addition to climate effects on transmission, weather also affects a microwave installation's physical integrity. Snow or ice accumulation on an antenna introduces critical weight considerations for the antenna's design, as well as for the components installed there.

Long-haul antennas generally employ a fabric enclosure, or *radome*, that protects sensitive components from wind or moisture infiltration. Ice shields offer additional protection from falling ice, either from the antenna itself or from positions above it (figure 8.12).

8.12: Ice accumulation on a radome-protected installation

Wind

The force of wind on an antenna structure is called wind load, and it can present a serious threat to tower-mounted equipment. Wind speeds rise with altitude, so a breeze at ground level can become a gale a few hundred feet up. This is why antennas are designed to ensure mechanical integrity under all anticipated environmental conditions, typically able to withstand 180 km/h (112 mph) winds without moving on their mounts. Above this speed, some flexibility may be permitted, with a topmost survival rating approaching 250 km/h (155 mph) wind speeds.

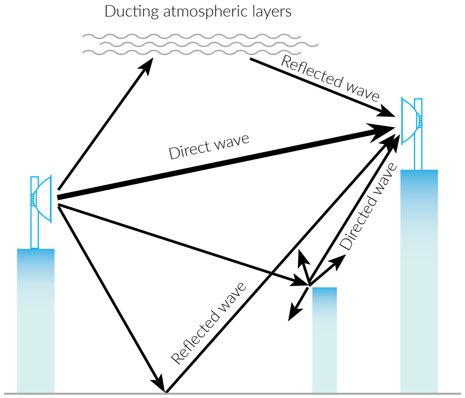
Far below these extreme limits, an antenna will flex and move slightly, even in moderate winds, within its engineering standards. While this helps maintain the integrity of the structure, it introduces an obvious challenge to LOS transmissions that depend on precise targeting between links. To ensure that this slight movement doesn't interfere with a successful hop between stations, these temporary misalignments must be factored into the antenna's power budget.

Lightning strikes

Installed in open, unobstructed locations, microwave antenna towers are natural targets for lightning strikes. If a strike passed through the antenna itself, serious damage to sensitive components would result. To avoid this danger, low-resistance earth-paths—in effect, lightning rods—are installed to direct lightning strikes away from critical components. For a full exploration of how to guard against lightning, see chapter 11.

Atmospheric effects

Atmospheric effects can disrupt reception, particularly for lower-frequency signals. Under some circumstances, a signal may essentially be received twice, first by its intended LOS connection, and then again as a slightly delayed echo of itself as a result of atmospheric refraction or ground reflection. The tiny timing difference can mean the signal arrives out of phase, in effect interfering with itself. This effect is known as multipath fading or dispersive fading, as illustrated at the right (figure 8.13).



8.13: Dispersive fading creating out-of-phase signal echoes—delayed signals bounce off the ground and vertical obstacles, and also refract in the atmosphere

8.14: A typical vertical space diversity arrangement

Option 1: space diversity

To counter the effects of dispersive fading, we can add a second, uncorrelated parallel microwave transmission path, separated vertically (figure 8.14) or horizontally.

Because the two paths don't share exactly the same space, their signals don't encounter exactly the same fading effects. The practical result is that the receiver has the option of accepting its signal from the path that happens to be less disrupted at the time.

Option 2: angle diversity

Another countermeasure is angle diversity, which requires only one antenna instead of the two. However, that antenna requires two vertically separated feed systems. While a less expensive option, angle diversity is also less effective than space diversity and is used only where a second antenna cannot be added to the installation.

Option 3: frequency diversity

Frequency diversity is another means of combating atmospheric or dispersive signal loss. A secondary, standby channel operates at a different frequency from the main channel. Since different frequencies propagate differently, two signals of different frequencies don't experience the same attenuation, doubling the chances of clear reception.

Flat fading
Total signal loss caused by atmospheric refraction. It is the result of a signal being bent completely out of its LOS connection with its receiver.

Flat fading

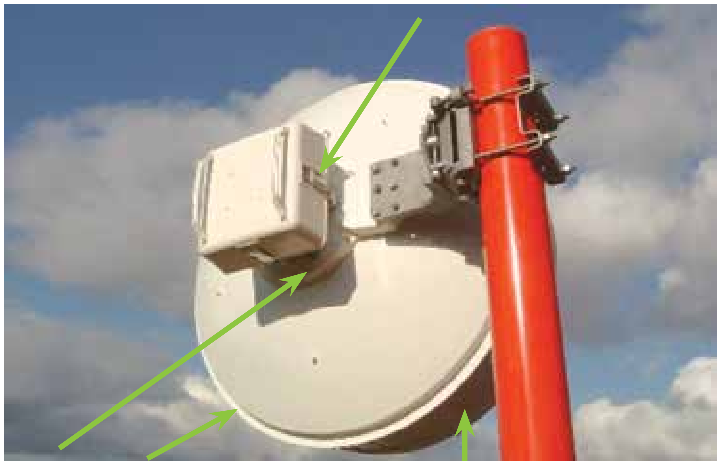
Flat fading is another atmospheric hazard for low-frequency signals. Unlike dispersive fading, the entire channel is attenuated because refraction has disrupted the LOS connection over the hop, so it misses the receiver entirely. A second, uncorrelated microwave path or increased power via ATPC can counter this effect.

Improving network reliability

Some of the reliability-limiting factors can be avoided by using compliant spec antennas from a reputable manufacturer. With the pressure to minimize total cost of ownership, it is tempting to purchase the lowest price antenna option, but you must also consider ongoing operations expenses in budget calculations. An inexpensive install may end up costing far more than a more expensive antenna with better characteristics for your application.

Noncompliant antennas are not simply identified by cheaper prices. They also include design problems that can spell trouble from day one (figure 8.15). Generally, they are:

- Not tested and feature non-repeatable designs
- Prone to deteriorate too quickly, resulting in RF leakage, moisture ingress and degrading metallic components
- Used with third-party add-ons for normal operation, which introduce new opportunities for corrosion, vibration and other loss of integrity.



8.15: Example of RF leakage in a noncompliant microwave antenna

The hidden costs of noncompliance

CommScope recently conducted a study to measure the cost and benefits of using lower-quality, noncompliant antennas. In this study, we examined three types in the 15, 18 and 23 GHz bands. In actual operation, the true costs began to emerge:

- **19% of the backhaul network failed** in the 15 GHz band
- **29% of the backhaul network failed** in the 18 GHz band
- **21% of the backhaul network failed** in the 23 GHz band

Obviously, these failure rates are unacceptable to most modern applications. Choosing a compliant antenna, even a more expensive one, offers benefits that can save money and hassles once the antennas are in operation, such as:

- Less potential external noise
- Less RX threshold degradation
- Longer hops
- More link availability
- More capacity
- More efficient use of the spectrum

In addition, there are other initial cost savings that aren't necessarily reflected in the antenna price itself, such as:

- Smaller antennas with lower shipping costs
- Lower landed cost
- Lower tower leasing cost

It all adds up to lower total cost of ownership, which makes good sense and means good business. There are a few common-sense steps you can take to avoid noncompliant antennas and assure your network's availability and reliability. They all start with choosing a reputable supplier.

1. Take advantage of your supplier's resources to demonstrate structural integrity under all anticipated environmental conditions.
2. Review the supplier's antenna interface design data and test range facilities for each integration type.
3. Avoid third-party add-ons that don't qualify at the integration level; the third-party supplier won't have this information, but your antenna supplier should.

This basic due diligence will pay off in reliability, speed and total cost of ownership.

Co-channel dual-polar (CCDP) operation
Using both horizontal and vertical polarity of a single frequency to double available bandwidth.

Network capacity and managing demand

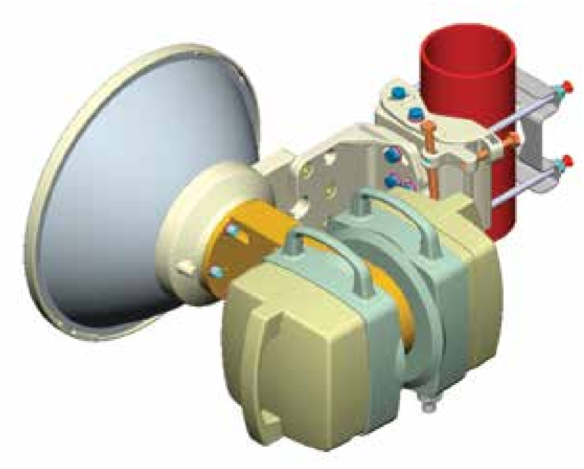
Simply put, capacity is a network's ability to handle transmission traffic. In the case of cell communications, this traffic means voice and data—often, a great deal of data. As capacity demands continue to rise with the spread of long-term evolution (LTE) and 4G mobile devices, smart planning becomes even more important to assure headroom for tomorrow's data-hungry applications.

Modulation. One way to boost capacity along a microwave link is called modulation. By employing different modulation schemes, more traffic can be squeezed into the limited bandwidth available when needed. The tradeoff is that higher modulation schemes require higher signal-to-noise performance to maintain the integrity of the data, boosting operating costs. Plus, any disruptive effects like those described above create bigger problems than they do for un-modulated traffic.

Adaptive modulation. Recently, adaptive modulation has become a universally adopted technique to help operators balance traffic and reliability needs. Adaptive modulation scales the amount of signal modulation employed as a function of the link's condition. So, if rain or other factors are present, modulation is dialed down to maintain error-free, if somewhat slower, traffic rates. When the link condition improves, modulation is automatically increased to take advantage of prevailing conditions.

Co-channel dual-polar operation. Another capacity-boosting technique leverages the polarization characteristics of microwaves themselves, which allow two streams of traffic to travel the same bandwidth at the same time—one vertically, one horizontally. This technique is called *co-channel dual-polar* (CCDP) operation.

CCDP is often used in short-haul antenna systems where an integrated dual-polarized antenna is created using an Ortho-mode transducer (OMT) to attach two ODU radios to a single antenna. This arrangement maintains a high level of isolation between the two signals for maximum clarity (figure 8.16).



8.16: An example of an integrated dual-polarized antenna

Microwave capacity

With all these capacity-boosting tools at our disposal, modern microwave backhaul data rates typically range between 32 and 155 Mbps (megabits of data per second).

However, as technology and techniques continue to improve, much higher data rates are becoming possible and economical. In the near term, 1 Gbps (gigabits of data per second) single-channel systems are coming online now.

The future of microwave backhaul

Explosive demand for mobile communications drives the need for cost-effective microwave backhaul, which, in turn drives new innovations. Old technologies are replaced by new, more efficient ways of moving data faster, more reliably and at less cost. Microwaves form the backbone of these new technologies.

For instance, legacy networks built on circuit-based transmission protocols maintain their connection regardless of how much, if any, traffic is actually being transmitted at any given time. This was once necessary to carry voice communications, but the world has moved on and this technology isn't efficient in our on-demand data world. Packet-based microwave radios encode traffic from multiple sources and routes it through IP over Ethernet, so it only utilizes bandwidth as it's needed, reducing wasted energy and capacity.

Capacity and coverage

Improved network coverage is another critical requirement for emerging mobile technologies, such as long-term evolution (LTE) and 4G mobile networks. Customer-level access is required in all regions if high-speed connectivity is to be available as a constant resource, and the ongoing rollout of base stations (known as macro-cells) offers more and more coverage to broad geographical areas.

At the same time, the capacity available from these macro-cells diminishes with distance from the base stations, requiring the addition of smaller coverage micro-cells to sustain capacity. Pico-cells represent a further layer of coverage for built-up urban areas. Both micro- and pico-cells require backhaul connectivity, and that means microwave links.

The techniques of tomorrow

There are currently a number of studies researching which type of backhaul medium will be most suitable for these new scenarios, and it seems likely that a mix of the various technologies will form the networks of tomorrow. Non-line-of-sight (NLOS) schemes using unlicensed bands offer one method of small-cell backhaul, allowing signals to turn corners and avoid obstacles in urban environments where LOS systems aren't as effective as they are in the open.

In other exciting developments, there seems to be great promise in the recently opened 60 GHz unlicensed band. At these high frequencies, the oxygen in the air itself can absorb signal power, making it suitable for short hops, often less than a single kilometer. While this may seem like a limitation rather than an advantage, an urban environment benefits from this short-hop option because they offer high data traffic rates and have such limited ability to interfere with one another from one pico- or micro-cell to another.

Lastly, the recent opening of the E-band spectrum (71-76 GHz, 81-86 GHz and 92-95 GHz) promises to open new avenues for high-capacity microwave backhaul. Operating under a light-licensing regime, very wide channel assignments (n × 250 MHz) are available to operators, making 1 Gbps data rates a real possibility without the restrictions of high-level modulation schemes.

With so many advances in recent years, and so many still to come, this is truly an exciting time in communications.

Backhaul makes modern communications possible

The ever-increasing complexity of modern communications networks demands more efficient and innovative ways of managing backhaul. In our wireless age, microwave backhaul moves the information that moves the world forward.

Though an efficient and cost-effective means of moving data through central processing, microwaves face challenges and limitations from weather, topography and interference from other nearby links. Smart planning and the right equipment can overcome these obstacles, allowing microwaves to connect us to one another wherever we may be.

As children, we first experienced the idea of backhaul as a length of string between two soup cans or the scratchy sound of a walkie-talkie. As adults, backhaul has become a key part of daily life as we depend on our cell phones, computers and other devices to connect with friends, family, colleagues and the world at large.

From strings to radio waves to microwaves, backhaul is the technology that keeps us all connected.

Chapter 8 summary

Microwave backhaul

- Communications moving through a centralized routing center
- Accomplished via links or “hops” from station to station

Microwave deployments

- Rely on line-of-sight between hop points
- Can connect multiple radios to antenna via paired ODUs

Issues affecting reliability

- Rain, snow and hail
- Wind loads
- Ice buildup on antennas
- Lightning strikes
- Dispersive fading

Avoiding external interference

- Coordinate with other links in vicinity
- Use manufacturer RPE to choose specifications

Avoiding trouble

- Choose a reputable supplier
- Look at entire cost, not just the purchase price

Maximizing capacity

- Adaptive modulation
- Co-channel dual-polar operation

Chapter 9

The energy that connects the world:
Powering wireless networks

Every year, our reliance on always-on technology grows. We expect to be able to place a call or surf the Internet with our cell phones at any time, under any circumstances. However, the electrical infrastructure that powers our networks has not kept pace with the explosive growth of cellular access—and certainly hasn't kept pace with our expectations of 24/7 availability.

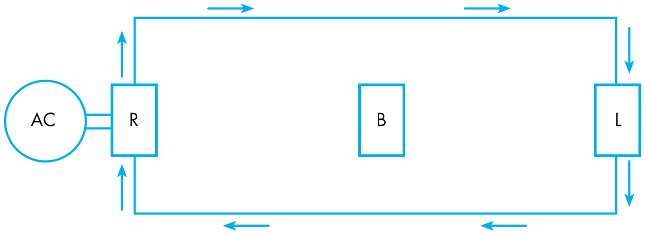
In previous chapters, we have explored some of the intricate and complex ways different components in a cellular base station come together to work efficiently and reliably. So far, the idea of powering these stations has been taken for granted. In real life, however, we don't have this luxury. Power supply connection is a very real challenge, and planning for the inevitable outages and interruptions is critical to keeping the network operating, no matter what complications may arise.

Direct current (DC)
An electrical current that runs continuously in a single direction, making it well suited for use in motors and electronic components such as semiconductors. Batteries also produce DC current.

Alternating current (AC)
An electrical current that changes polarity (direction) 50 to 60 times per second. It offers significant efficiencies when transmitted across power lines, making it the standard current for household use.

DC vs. AC power

The core technology that drives modern communications runs on *direct current* (DC) electricity. DC is different than the *alternating current* (AC) we use in our homes and offices. Since electrical power sent across transmission lines from power plants is AC, a device called a rectifier is needed to convert the AC current to DC before it can be used by the communications equipment.



9.1: Basic power system diagram—arrows indicate the DC current's direction

The rectifiers' output is connected to both the radio and its transmission equipment—the "load" for the current—as well as the backup battery equipment (figure 9.1).

Why go to the extra trouble of converting AC to DC? There are several reasons. First, most communications equipment includes semiconductors and other integrated circuitry that are specifically designed to operate with DC, such as:

- Telephone switches
- Microwave transmitters
- Fiber-optic transmitters
- Mobile radio and cellular systems

Another reason DC power is preferred for communications systems is its reliability advantage. Even the most advanced electrical grid can fail from time to time, and no one is immune to the possibility of power interruptions that may last for hours or days. When the outage occurs at a cell station, shutting down is not an option. So battery or fuel-cell backups are installed to allow continuous operation and these power sources produce DC power. This system is used for both cellular and conventional land-line telephone service, which is why you still get a dial tone even when your home's AC power is out.

DC power by the numbers

Communication equipment requires specific voltages of DC current. Most commonly, the requirements are positive 24 volts (+24V) and negative 48 volts (–48V). These high voltage values reduce their associated current and lighter current requirements allow for smaller and less expensive fuses, circuit breakers and cables.

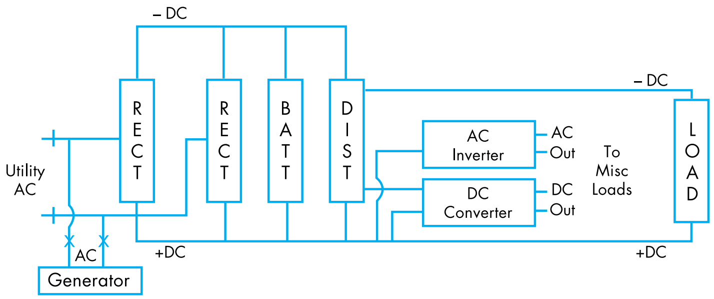
The +24V value evolved from the early mobile radio industry, back when equipment was designed to draw power from a +12V automobile battery or +24V truck battery, the same kinds of batteries used today.

Going beyond the basics

As mentioned above, the basic core components of a communication system's power connection are the rectifier, which converts AC current to usable DC current, and the batteries which assume the load when external power is interrupted. Once DC is online, however, we must consider the specific power needs, or loads, of different equipment. We need a means to distribute the correct voltages to each piece of equipment.

To make these adjustments, devices called DC-DC converters can modify the primary DC voltage to suit the needs of a piece of equipment that demands a different voltage. In the event that some equipment requires AC current, we can also include a device called an inverter, which changes DC back into AC. Because this all takes place behind the station's main rectifier, this reconverted AC power isn't subject to interruptions from the external power supply. A sample diagram showing all these components appears below (figure 9.2).

You may also notice an important new element appearing in this diagram: the generator. Generators supply AC power for the station's rectifiers if external power is interrupted. This keeps all systems operating and the batteries fully charged. There are several kinds of batteries and generators in common use. Selecting the right generator often depends on space, budget and operational expectations.



9.2: Block diagram of a basic telecommunications power system

Volt (V)

A measurement of electric potential difference between two points in a path. Voltage is sometimes referred to as "pressure," because it shares many characteristics with pressure in a water pipe.

The chemistry of batteries

At its most basic, a battery is an electro-chemical method of storing and releasing electrical energy. A battery contains chemicals that react with one another, producing DC electrical current as a byproduct. The specific chemicals and processes may vary—we will examine some common varieties below—but, on a fundamental level, all batteries operate on this core principle.

While the battery is receiving a charge from a fully operational system, it does not discharge any current. Rather, it consumes a small amount of DC from the power relayed by the rectifier. When this current is interrupted, natural processes kick in and the batteries discharge their stored DC power in accordance with the load placed on the circuit. Most importantly, this shift occurs seamlessly and leaves no interruption in current.

Reliable backup times usually range from two to eight hours, depending on the load. Since telecommunications providers must be able to specify expected operational times, choosing the best type and configuration of batteries is critical.

Lead-acid batteries

These are commonly used as backups for telecom power systems. They are highly compact relative to their output, and are the same kind you would find under the hood of your car. They are available in vented and valve-regulated forms (figure 9.3).

Flooded battery

VRLA battery

9.3: Vented (flooded) and valve-regulated (VRLA) batteries

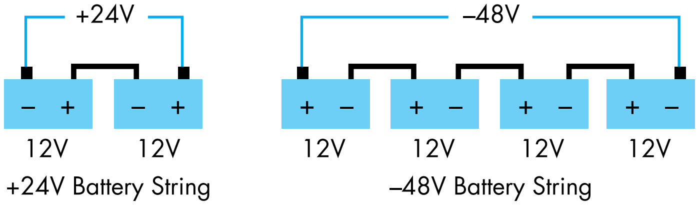
Vented (also known as **wet** or **flooded**) **batteries** are a mainstay of telecom central offices and switching centers. They maintain a charge for up to 20 years or longer. However, they demand a great deal of costly maintenance such as water treatment, spill containment and forced-air ventilation. These drawbacks make them less suited to remote cell base stations.

Valve-regulated lead acid batteries (VRLAs) are recombinant batteries, which means oxygen and hydrogen can recombine to prevent water loss. Because they don't need added water and can therefore be built in spill-proof containers with pressure relief valves, these are often called sealed lead-acid batteries. They are easier to ship, maintain and install, and cannot freeze like a flooded battery, making them the preferred choice for cell base station use.

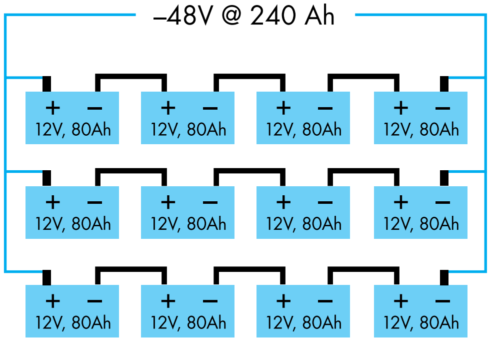
Battery cell configurations

Each battery is comprised of cells arrayed in electrical series. The number of cells used in a particular battery is determined by the overall required operating voltage and the voltage of each cell. For VRLA batteries, a standard voltage of 2V per cell is the norm so, to power a +24V system, 12 such cells must be connected in a series. Likewise, a –48V system requires 24 cells. Often, VRLA batteries are available in 12V blocks, like those seen in figure 9.4.

The arrangement of these batteries in series determines the voltage polarity. If each of the 12V batteries shown above is rated for 100 amp-hours, then each series string of batteries could be expected to produce 100 amps of current for one hour. Capacity is directly related to the size of the battery, but rather than spending more on larger batteries, we can achieve the same boost to capacity by adding more strings of batteries to the system in parallel as opposed to adding them in series. This option also provides safeguards against the failure of an individual battery, which would remove its string from the system altogether. By connecting in parallel, the spare capacity is already online and ready to maintain the current for its rated length of time. A diagram of sample parallel battery strings rated at 240 amp-hours, appears below. Note that if a battery failed in any of the three series strings, the remaining two strings would continue to supply steady power at 160 amp-hours (figure 9.5).



9.4: VRLA batteries configured in series for +24V and –48V applications



9.5: A multi-string battery configuration offering additional redundancy

This configuration also provides a convenient means of maintaining the batteries. Often, these strings will be installed with separate disconnection breakers, which make it easier to locate failures and isolate problems that could otherwise cripple the entire system.

Voltage polarity: positive (+) and negative (–) voltage

The + and – designations of +24V and –48V refer to which polarity of the battery circuit is measured; in terms of actual power produced, the distinction is meaningless.

Generators: the first line of defense

If batteries are the last line of defense against service interruption, generators are the first. Since batteries alone can only maintain operations for a few hours, longer AC service interruptions require a longer-term solution and that means generating our own power.

Unlike batteries, generators provide power by burning fuel. Like batteries, there are different types and configurations available. Which one you install depends on factors like space, cost and service expectations.

Since they operate outside the cell station's internal DC system, generators aren't considered part of that system. Because they supply the DC system's rectifiers with the AC they need, however, they're a vital link in assuring reliable operation. In the event the station must switch from external to generator-supplied AC power, an electrical device called a transfer switch shunts the load to the generator.

For stations with permanently installed standby generators, an automatic transfer switch (ATS) monitors external power levels and performs the changeover to generator power if the voltage drops below acceptable levels. View an example of AC generator. (Figure 9.6)

AC permanent genset

9.6: AC permanent generator

Generator fuel sources

You may have an emergency generator at home, or use one for electrical service in a remote location. Chances are that your generator runs on ordinary gasoline. Larger generators may also use compressed natural gas or diesel fuel, but the optimal generator for a DC system like a cellular base station is hydrogen fuel cell technology, for several good reasons.

Hydrogen fuel cells use proton electrolyte membrane (PEM) technology to generate DC power. We'll explore this later, but from a practical standpoint, hydrogen fuel cells offer several key advantages over their petroluem-fueled cousins.

Hydrogen fuel cells:

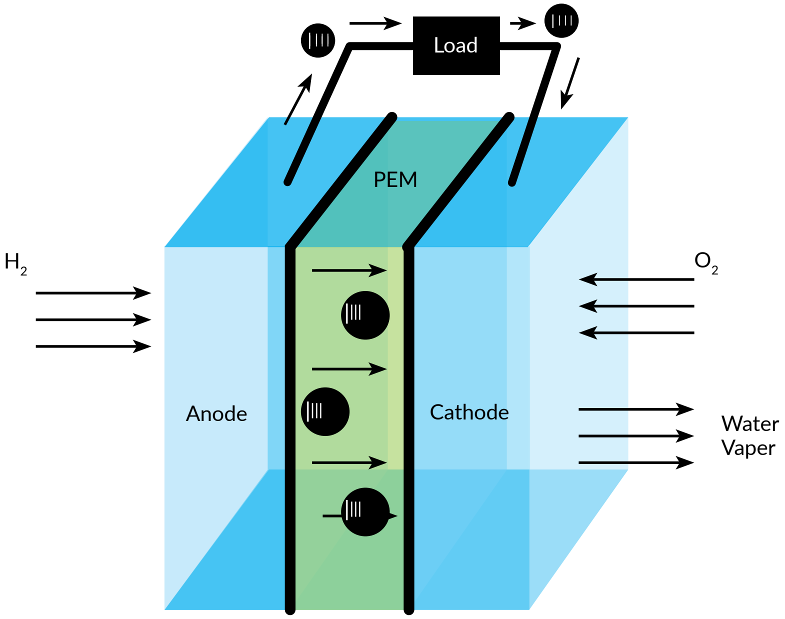
- Run on inexpensive, readily available hydrogen
- Produce very little heat, preventing damage to other components
- Offer higher efficiency than typical diesel generators
- Operate in ambient temperatures from −40°F to 122°F
- Are more compact than other fuel cell types
- Are quiet and non-polluting
- Have no moving parts, extending their operational life spans
- Require very short warm-up periods so they come online quickly

Generators in general, and hydrogen fuel cells in particular, can provide large amounts of steady, predictable power for extended periods of time.

The science of fuel cells

In a PEM fuel cell, hydrogen atoms are stripped of their negatively charged electrons at the anode end of the battery. This ionizes the hydrogen atoms, giving them a positive charge. The liberated electrons provide the actual DC to the connected equipment. Meanwhile, at the cathode end of the battery, oxygen combines with the hydrogen and electrons returning from the circuit, creating water (figure 9.7).

As long as the system is supplied with hydrogen and oxygen, the fuel cell will produce a predictable amount of current.



9.7: Basic operation of a hydrogen fuel cell

Hydrogen fuel cell installation

Hyrdogen fuel cell installations include three main components: hydrogen storage, a fuel cell stack and power module, and an integrated bridge battery. A typical layout is shown in figure 9.8, along with a view of an actual installation in figure 9.9.

Hydrogen storage

Like many liquid or gaseous fuels, hydrogen is stored in tanks. For a fuel cell deployment at a cellular base station, this storage would usually comprise 8 to 16 cylinders of compressed hydrogen.

Fuel stack and power module

Because of the power demands of base station equipment, a single fuel cell cannot provide enough power by itself, so multiple cells, called a stack, are linked together in a fuel cell power module (figure 9.10). This linked arrangement is similar to the multiple battery configurations discussed earlier.

Bridge batteries

While hydrogen fuel cell generators warm up quickly and are ready for service shortly after an AC power interruption, there is a brief bridging period when batteries must carry the load alone. These integrated battery backups provide the necessary power to cover the brief time needed for a fuel cell to come online.

Fuel supply and maintenance

Hydrogen fuel cells are efficient, quiet, reliable and long lasting. But, like any generator, they require a supply of fuel to operate. When the hydrogen supply dwindles, an automatic alarm alerts the system's operator that fresh supplies are needed. To preserve hydrogen, fuel cells are designed to shut down once external AC power has been restored. They are then ready to engage the next time an interruption occurs.

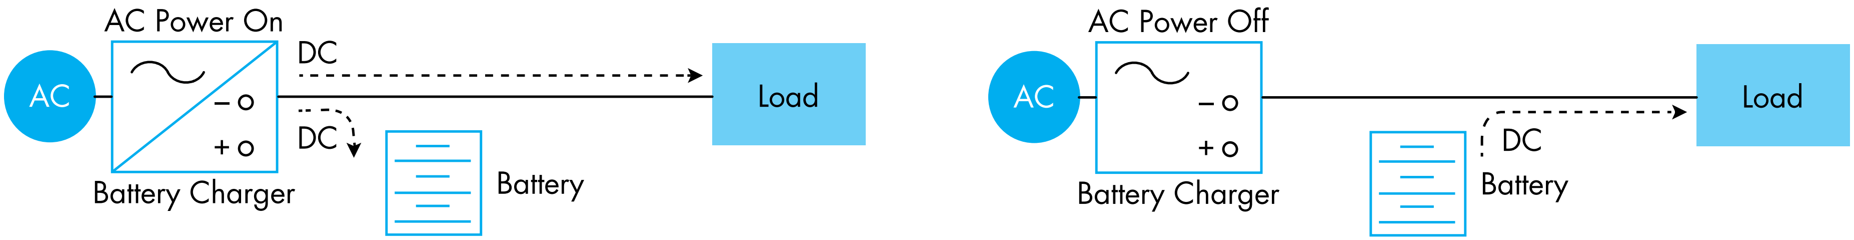
With no moving internal parts to wear out and very little heat radiation, fuel cells require very infrequent maintenance, often amounting only to an annual inspection of their oxygen intake filters and radiator fluid levels.

Rectifiers: the AC-DC interface

Once beyond the external source of power, whether it's commercial AC electrical service or an AC generator, the rectifier is the core of the system's DC power distribution needs.

The rectifier is designed to provide an output DC voltage level that maintains the battery charge. This level is called float voltage, and it supplies the equipment load as well as a trickle charge to the battery. In the event of an AC power interruption, the rectifiers go offline and the batteries automatically kick in, providing the same level of power to the rest of the system. When external AC power is restored, the rectifiers re-engage and the batteries return to their trickle-charging state (figure 9.11).

In practical deployments, multiple rectifier modules are usually required to supply power for the station's load. Rectifier modules are connected in parallel, letting each one share an equal part of the load, a practice known as load sharing. With load sharing, operators can design in a degree of redundancy to guard against individual rectifier module failures.



9.11: External AC power on (float mode) and off (discharge mode)

How redundancy adds up to reliability

For a –48V application with 200 amps of load, an operator may choose to install five 50-amp rectifiers.

Why add a fifth, when four would provide the requisite 200 amps? To ensure N+1 redundancy. Arranging multiple rectifiers in parallel allows load sharing to even out and shift the load.

Choosing the right rectifier

The first consideration in deciding which rectifier will best suit a given installation is the kind of AC power it will receive. Switchmode rectifiers are the preferred choice for cell and microwave sites since they can support multiple AC inputs and have a broader operating range—from single-phase to three-phase inputs. This flexibility means fewer rectifiers are required, saving money, space and maintenance.

Another consideration is the required output voltage. As we've seen, the rectifier must be able to output the voltage required by the station's equipment, that is, +24V or –48V. The amount of current must also be sufficient to power all the loads, such as the radio, transmission equipment and battery backup.

9.12: Example of a typical rectifier

Distributing the power

The rectifier is merely the first stage in the DC power system. Once converted, the power must be distributed to the many component loads within the system. As mentioned above, these loads include core elements like the radio, transmitter and battery backup, but they can also include secondary systems like lighting, security networks and HVAC systems (figure 9.13).

In the most complex installations there may be so many components that up to 80 circuit breakers are required to manage them.

The most visible parts of the distribution system are the fuses or circuit breakers, which safely distribute DC power from the rectifier to each individual load. Fuses and breakers are connected in series between the power system and their loads, protecting them from short circuits and damage from overload conditions. They also provide a safe, simple way to manually shut down individual components or batteries for service, maintenance or replacement.

Fuses vs. circuit breakers

While both fuses and breakers provide overcurrent protection, they do it in different ways. Fuses are designed to melt under unsafe currents, physically breaking the connection between the power source and the load. Circuit breakers have internal switches that pop to the "off" position under unsafe conditions, again providing a physical break in the circuit.

Sensitive wireless equipment requires "fast blow" fuses or short delay-curve breakers to provide the needed protection. Fuses are generally used for lower loads and offer the advantages of lower cost, greater flexibility and fast action. Circuit breakers are preferred for larger loads and do not require replacement every time they are tripped. Some typical examples are shown to the right (figure 9.14).

Because complex cell sites can require from 24 to 80 breakers of varying capacities, wireless carriers have adopted modular distribution structures that can accept a wide range of breaker sizes.

9.14: Common types of telecom fuses and circuit breakers

Surge protection

Typical variations in AC power are not the only threat to a cell site. Electrical events like lightning can also produce excessive voltages and currents, events known as electrical surges. Surge protection devices (SPDs) are incorporated to reduce the effects of these surges on sensitive electronics (figure 9.15).

An SPD features a non-linear voltage-current characteristic that reduces unsafe voltages by increasing the conducted current. In this case, a cell site's SPD operates on the same principle as a surge protector does in your home, safeguarding expensive electronics from lightning-induced surges.

9.15: Typical surge protector devices (SPDs); image courtesy of Raycap Corporation

Bus bar conductors

The cell site's distribution system is supported by the bus bar conductors, which physically connect the rectifiers to the batteries and DC loads. There are two bus bar connectors: the **charge bus** and **battery return bus.**

> The **charge bus** is a current-carrying conductor that connects the rectifier's output to the battery string. For instance, in a –48V system the negative rectifier lead would terminate on the charge bus along with the corresponding negative lead of the battery.
>
> The **battery return bus** provides a common return point for the loads connected to the power system. This common point is grounded to provide a low-impedance path for transients and noise, and offers a ground reference to all connected equipment.

The shunt

In a distribution system, a shunt is a low-resistance resistor designed to provide a specific voltage drop at a particular level of current. As the current passes through the shunt, it develops a small voltage proportional to the amount of that current. This voltage drop allows an operator to calculate the current flow in the system.

Battery disconnects

Battery disconnects are switches installed on a battery string that allow easy disconnection for maintenance or replacement. Some disconnects incorporate safety measures such as overcurrent fusing or breakers.

Load disconnects

Low-voltage disconnects (LVDs) are designed to respond to low voltage conditions in the circuit. Low-voltage load disconnects (LVLDs) can disconnect individual loads, while low-voltage battery disconnects (LVBDs) can disconnect a fully discharged battery.

LVDs serve three main protective functions:

1. They prevent damage to sensitive electronics caused by low-voltage (and hence, high-current) conditions
2. They prevent permanent damage to the battery from over-discharging
3. They prioritize which components are disconnected, and in which order, preserving limited function when necessary

Supervision, monitoring and control

Modern telecommunication power plants are equipped with electronic monitoring and control systems, generally called **controllers.** They keep track of system voltages, currents, temperatures and other key indicators. They also allow operators to make adjustments from a central monitoring point, usually on the power plant itself, on the distribution cabinet or in a rectifier slot (figure 9.16).

9.16: A system controller interface displaying voltage, amperage and alerts

With a modern controller, there is very little you can't learn about your cell site's power system performance.

This controller centralizes several key functions in a single, simplified interface, including:

Plant control. Control functions are extended from the supervisory panel to control other power system components. These panels communicate directly with the rectifiers, and in some cases can coordinate the sequenced restart of all rectifiers to prevent power surges during switchovers from external AC to a backup power source.

Manual equalizing. This allows a user to engage all rectifiers in equalize mode at once. This is useful for maintenance on VRLA batteries, equalizing cell voltage within a battery string.

High-voltage shutdown/overvoltage protection (HSVD/OVP). Controllers can automatically shut down rectifiers when DC output overvoltage conditions are detected, avoiding costly damage to load components.

Low-voltage disconnect (LVD). If a low voltage condition is detected in the backup batteries, the controller can open additional contacts to equalize voltage and close them again when levels equalize.

Battery temperature compensation. The controller can adjust rectifier output to meet the temperature-driven voltage needs of the batteries.

Charge current control. This feature limits the current flow to a battery when it begins recharging after a power interruption. By keeping the battery from recharging too quickly, it prevents overheating and prolongs life.

Battery diagnostics. The controller can estimate the "health" of the battery and predict how long it will provide power based on its charge status.

Alarm monitoring. The controller monitors critical functions like distribution and battery fuse alarms, rectifier failures, converter failures and so forth. It reports these alarms by way of network backhaul interfaces and LED indicators. Some units include audible alarms as well.

Status monitoring. The controller can measure and compare the battery charge to the system load via an external shunt.

Plant history. Controllers can log power system details over a span of time, including such statistics as thermal performance of outdoor enclosures, battery cell states, or variations in AC input experienced by the rectifiers.

DC-DC power conversion

Some wireless sites require multiple DC voltage outputs, such as +24 VDC and −48 VDC. One solution is to install a second rectifier plant, but doing so comes with the burden of including a second battery backup array as well, which consumes considerable space and adds cost.

Another solution is to use a DC-DC converter system, an electronic power conversion device that changes a DC input voltage to a different DC output voltage. Below, you can see where a DC-DC converter system is connected in series between the main DC power system and the site's load (figure 9.17).

A DC-DC converter system actually consists of multiple DC-DC converters arranged in parallel. It may also incorporate many of the same functions as the primary DC power system, such as distribution. It also has dedicated fuses or circuit breakers, isolating it from the rest of the system.

9.17: A DC-DC converter system connected in series to a cell site's power system

Since a DC-DC converter system does not have an associated battery connected to its output, it isn't bound by a battery system's requirement for precise output voltage. However, since it is necessarily energized by the primary DC power system, that demand must be figured into the power system's initial design.

Dual-voltage power plant using DC-DC converters

Ordinarily, a DC power plant's rectifiers and batteries supply consistent power for a single voltage requirement. If two requirements exist at the site and the demand is heavily skewed toward one voltage or the other—either predominantly +24V or −48V—the secondary voltage may be supplied through the addition of a DC-DC converter system.

Because the conversion takes place between the rectifiers/batteries and the load, the secondary voltage will still receive all the backup support of the primary voltage in the event of external AC service interruption—and only one set of backup batteries is required (figure 9.18).

Advantages of converting voltage

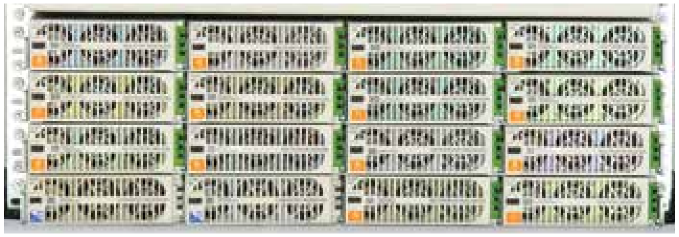
Modern DC-DC converters are essentially “plug and play” devices that are designed to fit in the racks alongside rectifiers and other converters (figure 9.19).

This approach offers communications providers the greatest flexibility in adopting next-generation technology, offering new services while maintaining older standards. As the deployment of the newer technology grows, additional converters can be added to the system to increase the secondary voltage’s share of the power supply. It should be noted, however, that doing so may require upgrading the rectifier capacity as well, while making sure to maintain the usual redundancy margin.

Disadvantages of converting voltage

On the downside, converting to a given voltage is inherently less efficient than drawing that voltage directly from the rectifiers, so losses increase as more and more DC power is converted away from the primary voltage.

Also, many traditional power plants cannot support the direct addition of converters to their systems. To draw two voltages in these instances, a separate converter plant must be installed. The converters draw power from the existing DC power plant via fuse or breaker positions in the distribution system, just like any other load device. This reduces the number of available distributions for the primary voltage equipment at the site.



9.19: Converters and rectifiers occupying adjacent power shelf slots

Mapping the positions

Since a single power plant can generate varying amounts of both primary and secondary voltages, the need arises to assign numbers to the distribution positions of each voltage. A selectable voltage distribution panel makes this organization possible (figure 9.20).

Integrated power systems

So far, we have focused on the individual components that comprise a cell site's power system. With so many components, you can imagine how quickly the space limitations of a site's shelter or cabinet become an obstacle.

To address these space limits, **CommScope** produces *integrated power systems* with several components built into a single device, and suited for installation in a single rack. This approach is increasingly common in modern cell sites.

A typical integrated cell site power system includes one or more shelves of rectifiers along with one or more shelves of DC-DC converters. This integrates power conversion and power distribution functions, connecting them with bus conductors. The distribution system contains an integrated DC bus, fuses or breakers and cabling tie-downs to distribute power to the load (figure 9.21).

Cell site power requirements range from 100 amps to several hundred amps of primary DC power. In +24V applications, these systems are configured to deliver 1,000 to 1,200 amps of primary power; −48V applications, about 600 amps. This may seem like a great deal of capacity, but the actual power consumption is typically far less than the system's theoretical capacity.

Since integrated power systems feature modular design, additional power can be added simply by plugging an additional rectifier into a vacant rack slot. Likewise, if there are secondary loads that use different voltages such as adding a +24V radio to a −48V system then DC-DC converters can be added to open slots to accommodate those needs. This is particularly useful in an age where radio technologies evolve at a rapid pace.

DC-AC inverter

Some of the equipment operating at a cell site may require AC current from battery backup supplies. Since the entire system is built around DC power, a DC-AC inverter is needed to provide the necessary AC voltage (figure 9.22).

There are two basic types of inverters:

> **Offline inverters** feature an AC input and an AC output with a standby DC line connection available. This is the type generally used in cell site applications.
>
> **Online inverters** feature a DC input and an AC output with an optional AC standby line available.

Like DC-DC converters, the input for a DC-AC inverter is supplied by the primary power plant. Like converters and rectifiers, inverters are often installed and configured for redundancy. A static switch maintains equalized voltage to the load by switching automatically between external AC power and the inverter's AC power. This switching is done instantaneously, assuring no interruption in operation.

Along with the static switch, many systems also include a maintenance bypass switching panel in an inverter installation, which allows an operator to power down an inverter for servicing or replacement without disturbing the system's load. During this power-down time, however, the system load is entirely dependent upon external AC power.

Remote radio head (RRH)
A recent design advance in base station architecture that separates a cell site base station's RF and baseband functions for improved efficiency.

AC power sourcing flexibility

With ever-increasing utility costs, the ability to combine power from renewable sources with utility power is another aspect of power flexibility. To address this, some rectifiers can accept AC power from attached solar panels or wind turbines just as easily as they can draw it from the utility's transmission lines. An illustration of this flexibility is shown below (figure 9.23).

Architectural improvements to power management

Significant power losses occur as a signal moves from the radio transmission equipment in a cell site's base station shelter to the antenna up on the tower. These losses are a natural consequence of traversing long stretches of coaxial cable. However, the simple architectural change of moving the transmitter and amplifier—known collectively as the radio head—from the shelter to the tower eliminates these losses and reduces power requirements. This design is called the remote radio head (RRH).

The baseband equipment remains on the ground and external AC power still enters at the cabinet or shelter. But with the transmitter amplifier mounted adjacent to the antenna on the tower, more space is freed up and less heat management is required.

Because of its exposed location, the tower top is not suitable for the battery backups, but other RRH equipment can be easily sealed against the elements. Instead of coaxial cable running up the tower, now only power transmission lines are needed. Below are two possible methods of providing power to the RRH (figure 9.24).

As useful as this design is, it also introduces new challenges. For instance, since the battery backup is now located far away from the critical components in the RRH, a heavier gauge of power transmission line is needed unless the power is converted to a higher voltage down at ground level and then converted back to the needed voltage (+24V or −48V) at the RRH itself.

This arrangement sometimes uses "line power" equipment, which is now available for these applications. With line power, the ground-level voltage is increased to +/−190 V DC, reducing the current and thereby reducing transmission loss (figure 9.25).

Cell site power system configurations

Different cell sites store their power equipment in different ways. Some sites have equipment shelters at the base of the cell tower. Inside these climate-controlled enclosures, equipment is mounted in equipment racks, with an integrated power system in one rack and battery strings in another, and radio equipment in still another.

Other sites place integrated compact equipment in outside plant (OSP) cabinets. This approach offers less space and fewer opportunities for environmental management, so only components specifically designed for OSP cabinet environments can be installed. It is common practice to keep power and radio systems in separate cabinets. Because of their size, often batteries will have a dedicated cabinet as well. A few examples of OSP cabinets are shown in figure 9.26 and 9.27.

Keeping the power and communication flowing

A lot of thought, planning and effort is required to deliver and support our always-on, 24/7 world of communications. When power outages occur, as they inevitably do, it falls to forward-thinking engineers and companies like **CommScope** to put effective, reliable contingencies in place.

Many of the same systems that keep your home electronics in good working order like battery backups, circuit breakers, DC converters and surge protectors also keep our national cellular backbone in a state of constant readiness.

Interruptions in power shouldn't mean interruptions in our lives, and with the technology and expertise of **CommScope** and our partners in the communications industry, they don't have to.

9.26: Integrated cell site battery only cabinet

9.27: Integrated cell site power and battery cabinet

Chapter 9 summary

Powering wireless networks

- DC vs. AC power
- Cell site equipment requires DC power
- Rectifiers convert AC to DC

Batteries

- Lead-acid batteries are available in flooded and valve-regulated versions
- Backup systems built of batteries stringed in series and in parallel

Generators

- On-site power generation
- Hydrogen fuel cells

Distribution

- Fuses, circuit breakers
- Surge protectors
- Shunts
- Battery and load disconnects

Integrated power systems

- Combine multiple elements in one device

New efficiencies

- Dual-voltage power plants
- Remote radio heads
- "Line power" voltage conversion

Chapter 10

Successfully planning against failure:
Reliability in wireless systems

It's simply a fact of life that items left out in the elements will become more susceptible to problems as a result of such exposure. Outdoor furniture ages more quickly than indoor furniture, the car parked at the curb shows more wear than the car kept in the garage. As a matter of necessity, a home's exterior paint will need refreshing more often than its interior. The elements, as a rule, are harsh.

Planning for environmental punishment is also a key concern for cell site operators, as new efficiencies that wring more work from every watt often mean placing components farther out into the network, and that means placing them outdoors, high on antenna towers. The same degrading effects that peel a house's paint work relentlessly against the sensitive electronics that drive modern cellular communications.

The precise balancing act of increased component failure rates against operational efficiencies has led to a revolution in how cell towers and cell systems are developed and built.

CommScope is at the forefront of this new network architecture and its impact on reliability. We offer the tools and expertise to help operators maximize redundancy, improve weatherizing and plan for system component failure and systems all over the world.

Reliability
The probability of a device working correctly over a defined length of time, operating under specified conditions.

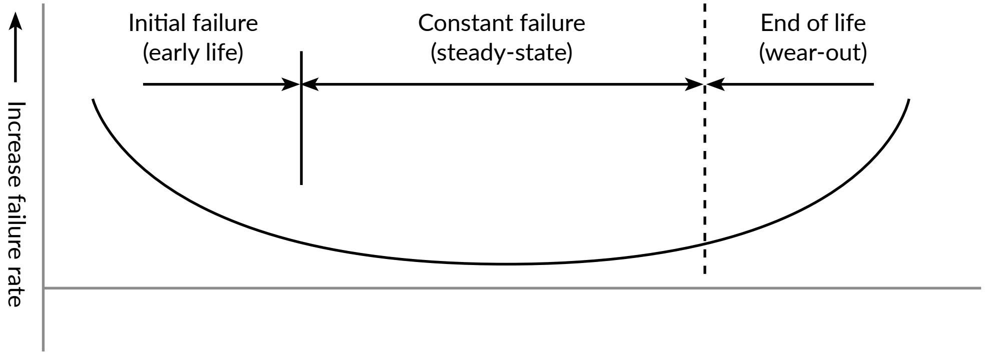
Reliability, objectively defined

In everyday conversation, reliability usually refers to your experience with a device or service. It's somewhat subjective in that no two people have exactly the same experience, and they don't react in the same way when a problem does occur.

For instance, your home Internet service may occasionally go down for a few minutes in the middle of the night, but since you're not using the Internet when it happens, you would refer to your service as highly reliable even though it occasionally fails. Another person might need a stable connection during a particular time of day and experience an Internet outage during that critical moment. Even though the interruption may last only seconds, that person would describe his connection as unreliable.

In engineering terms, however, reliability takes on an entirely new meaning. It has an objective, empirical value based on study, analytics and calculation. In this sense, reliability is defined as the probability that a product or service will perform as it should at any given time, under specific conditions. In engineering, "failure" is something to be anticipated, controlled and compensated for via system redundancy.

Generally, reliability rates can be defined with a classic bathtub curve, so named for its bowl-like shape (figure 10.1). As you can see, it predicts higher failure rates at the beginning and ending of a device's life cycle. For any given device, this graph provides a general guide as to its rate of failure—decreasing initially, and increasing during end of life.



10.1: The reliability "bathtub curve," showing the failure rate over the operational life of a device

The three stages of component life introduce three common causes of failure:

1. **Early-life initial failure** may be due to manufacturing problems, incorrect installation or damage during shipping.
2. **Steady-state constant failure** indicates random failure as a normal function of operation. This is the stage we are most concerned with in this chapter.
3. **End-of-life wear-out failure** occurs when fatigue, corrosion or other factors accumulate to the point where failure becomes more and more likely.

Determining when a device's end-of-life stage occurs depends on complex computations. For example, one must take into account known life expectancy of the device's main components, such as motors and fans with moving parts that are eventually subject to mechanical wear.

Similarly, electronic components also have life expectancies. For example, electrolytic capacitors used in wireless electronics are subject to degradation from high temperatures and AC ripple currents.

Quantitative reliability predictions

As you might expect from a complex wireless communications system, predicting likelihood of failure is a complicated process, but a necessary one. There are several methods:

1. Collection of empirical field data from customers
2. Accelerated life testing data
3. Prediction models based on "parts count" method
4. System availability models for large systems with internal redundancy

Each method offers different advantages. The "parts count" method, for instance, is particularly useful for new product designs, even before the product moves beyond its design stages. This method applies established life cycle information for the components used in the design—the steady-state failure rates indicated in figure 10.2—to create an aggregated model of potential failures.

This computation relies on industry software reliability prediction tools such as Telcordia SR-332 Reliability Procedure for Electronic Equipment. It adds up individual component failure rates and applies designer-specified multipliers accounting for specific temperature, electrical stress, production quality and environmental conditions to yield a final, steady-state failure rate for the component. The various stress parameters are:

- Stress factor for operation is de-rated from specified limits
- Temperature factor (often adjusted up or down from a reference point of 40°C)
- Quality factor accounting for supplier and process controls
- Environmental factor accounting for indoor vs. outdoor conditions

From such prediction tools, a designer can compute a predicted failure rate with a 90 percent or greater confidence limit, which means at least a 9-out-of-10 chance that the actual failure rate will be no higher than predicted. These estimates usually reflect conservative numbers, making them highly reliable predictors.

Stress factors

Of the several stress parameters, perhaps the most critical factors in predicting reliability in the wireless communications industry are temperature and environmental stress.

Temperature factor, more specifically operating temperature, is the sum of the ambient temperature and the temperature of the heat produced by the component itself. In practice, a 10°C increase in operating temperature can double the likely failure rate. Likewise, reducing the temperature by a similar amount can reduce predicted failure rates by up to 50 percent.

Environmental factor is just as important as a predictive element. For example, an outdoor environment introduces a multiplier of 1.5 to 2.0, depending on the outdoor application. This factor accounts for variations in temperature, vibration and other environmental variables in an uncontrolled outdoor deployment versus the same equipment in a climate-controlled enclosure. Recent data suggest that a 1.5 factor is typical for outdoor wireless equipment such as tower-mounted antennas and remote radio head (RRH) equipment. Much of this data was collected by monitored RRHs.

Water ingress protection starts with the careful analysis of points of ingress, design considerations for protection of critical RF connection points, formulation of condensation and management of condensation. Addressing each element often means tradeoffs between cost and efficiency in the design.

The final product of the reliability prediction tool includes detailed, part-by-part information such as that shown on the right (table 10.2).

Part number	Category	Unit FR (FITs)	Quantity	90% CL Failure rate (FITs)	Ref des
7094037	Capacitor	0.21	1	0.26	C37
7131706	Resistor	0.57	15	9.42	R3, R44, R6, R20
7131748	Resistor	0.57	3	2.10	R150, R151, R152
7131797	Resistor	0.57	9	5.80	R1022, R243
7144735	Capacitor	0.21	10	2.24	C152, C162
7144739	Capacitor	0.21	2	0.49	C58, C740
7164258	Miscellaneous	3.80	5	25.82	AT1, AT2
7165048	Resistor	0.57	1	0.80	R126
7500917	Resistor	0.57	1	0.80	R23
7501483	Resistor	0.57	1	0.80	R135
7512949	Capacitor	0.21	1	0.26	C1053
7541771	Integrated circuit	6.02	2	16.66	U1007, U1011
7563383	Integrated circuit	6.02	1	9.31	U1017

10.2: Example of a component reliability table

Measuring reliability

As mentioned above, reliability is the probability that a device will perform correctly under defined operational conditions over a specific span of time. But supporting this general definition are several practical ways of measuring reliability in real-world applications.

Mean time between failure (MTBF) is the time between two consecutive failures. This is the most common definition for reliability. MTBF is expressed as the inverse of the failure rate.

MTBF = 1 / Failure rate = 109 / FITs.

Mean time to repair (MTTR), sometimes called mean time to restore, is the time needed to repair or replace a failed component and restore its function. This includes procurement and travel time, so the figure is comprehensive in its scope.

Availability (A) is the percentage of time the system as a whole operates normally. When someone refers to "4 nines of reliability," they mean "99.99% uptime" (table 10.3). Availability is a function not only of how often a component fails, but also how long it takes to restore service when it does fail, so it figures in both MTBF and MTTR.

A = MTBF / [MTBF + MTTR]

When describing the reliability of an entire system, availability is a more useful measurement. That's because redundancies built into the design may tolerate some individual failures without seriously compromising the function of the system as a whole.

Unavailability (U) is the flipside of availability, in that it expresses the percentage of time a system is not working properly. Also, like availability, it can be calculated as a function of MTBF and MTTR.

U = MTTR / [MTBF + MTTR]

As you may expect, A + U always equals 100%.

Downtime (DT) is derived from unavailability and expressed as the average amount of time per year the system will be in an unavailable state. Since it measures failures that often last only minutes, and expresses them as a percentage of a full year, we simply multiply the unavailability percentage by the number of minutes in a year, or 525,600.

DT = U x 525,600

To illustrate, consider a system with 99.99% availability, or "4 nines." That means its mathematical value is .9999, resulting in a U value of .0001. Multiplying .0001 by 525,600 yields an expected annual downtime of 52.5 minutes per year, or less than a full hour. This is a key indicator in overall service quality (table 10.3).

Percent availability	Number of nines	Downtime (minutes/ year)	Service quality level
99%	2-Nines	5,000 m/y	Moderate
99.9%	3-Nines	500 m/y	Well managed
99.99%	4-Nines	50 m/y	High availability
99.999%	5-Nines	5 m/y	Very high availability

10.3: Service quality measured by uptime; more nines mean more availability

Failures in time (FITs)
The number of expected component failures per billion operating hours.

Availability on a systemwide scale

Because of the vast number of components that make up a wireless communications system—each with their own failure rates, redundancies and importance to overall operation of that system—predicting long-term performance of the system as a whole can be quite a challenge.

From a design standpoint, cost constraints make it impossible to build components that are not subject to some degree of failure. Therefore, the design must incorporate redundant subsystems to avoid complete system unavailability due to any single component's failure. Properly implemented, these subsystems will allow the system to continue functioning at full performance, even in its degraded state, until repairs can be economically performed on the failed component.

Budgeting for failure

Dividing a system's functionality into subsystems allows a "reliability budget" to emerge. By breaking down the complex whole into manageable segments, subsystem reliability can be more easily modeled based on its parts count or by another appropriate method. Then, the likelihood of failure of the entire subsystem can be modeled to learn its effect on the overall function of the system itself.

In a practical example, consider the mass of electronic components mounted atop a cell site tower. The system can be broken down into subsystems involved in the transmit path, the receive path, the power system and other related functions. Each of these will have a maximum allowable failure rate assigned based on its importance to the operation of the system. So the site's designers can plan accordingly, the overall reliability budget is split up and allocated where it is needed most.

In practical applications, these models are more concerned with the functioning state of a system or subsystem, rather than with the actual hardware or software itself. At this level of planning, MTBF and MTTR become more meaningful descriptors of reliability than failure rate alone.

Failure mode, effects and analysis (FMEA)

Given enough time, component failure is a certainty. Where and when it occurs, however, is a variable that must be modeled to be predicted. That means a lot of what-if scenarios, not only of component failure but the effect of that failure on its subsystem and the effect of that subsystem on the system as a whole. For this kind of analysis, failure mode, effects and analysis (FMEA) is a simple, table-based method of measuring these variables together.

The FMEA for a particular system lists each failure mode and its effect on overall system performance. Failures that result in total loss of service are combined to calculate the system's total availability, while failures that cause only minor effects on service are combined to calculate the system's partial availability.

Fault-tolerant design

Redundancy is the key to boosting availability within a system without requiring the subsystems to be more reliable themselves. Redundancy schemes vary by application, but they all have one thing in common: on-demand access to a device or service that can assume the function of a failed device until it can be repaired or replaced. Sometimes this includes a spare component; other times it means shifting load to other systems. Common redundancy schemes include:

- **Active/hot standby,** a spare component built into the system that operates all the time and can assume more load when needed due to primary component failure
- **Active/cold standby,** a spare component built into the system, which only comes online in the event of failure, with a possible interruption in service
- **1 + 1 load sharing,** providing two active routes for communications so one will be available in the event that component failure causes an outage in the other
- **N+1 load sharing,** providing a standby alternate route for communications to assume the load in the event that component failure causes an outage in any of the other routes

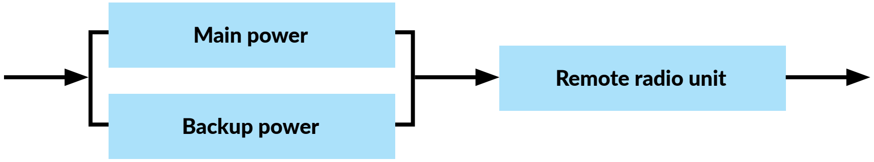
The downside of adding redundancy is increased cost. Therefore, redundancy should be added in circumstances where benefits outweigh costs.

The reliability block diagrams

Another widely used approach to measuring system reliability is the reliability block diagram (RBD). Unlike the lists of the FMEA table, it graphically shows the interconnections between subsystems on a conceptual level and how redundancy measures are integrated. Also, unlike the FMEA table, these element "blocks" are described purely by function, not by individual component; the system's reliability depends on how these blocks are connected. Arrows represent the direction of information flow, but may not necessarily correspond to the physical direction of current in the system.

How the RBD shapes up depends on the kind of system architecture under consideration. A typical architecture may include both redundant and non-redundant subsystems, as shown in figure 10.4.

An RBD is extremely useful in predicting system reliability, but it does have disadvantages. The main limitation is its static nature: it can only predict individual failures without accounting for cascading effects throughout the system as it continues to operate in a degraded state.



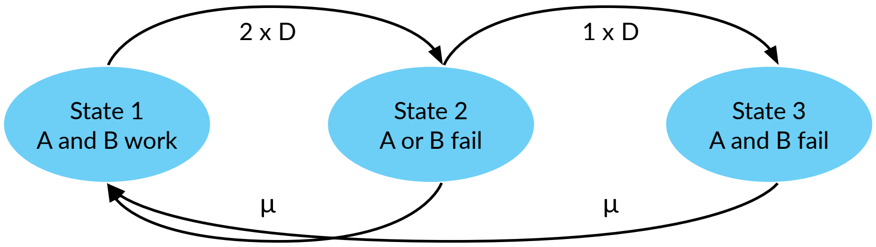
10.4: A simple RBD showing redundant power and non-redundant radio unit

State transition diagram (Markov Model)

In non-redundant systems, there are two states of being: working and not working. Transitions between these two states are defined by failure rates (1/MTBF) and repair rates (1/MTTR). Between these two measurements, availability can be easily determined.

However, more complex and more fault-tolerant systems have many levels of operational efficiency. We have referred to systems operating in degraded states, or a state of partial failure. To measure the reliability of these complex systems, the Markov Model defines all possible degrees of a system's operation and maps every state transition involved in making those states occur.

To illustrate, consider a simple system with two subsystems, A and B, each with the same failure rate (figure 10.5). As you can see, there are three possible operating states: fully operational, partially degraded and complete unavailability.



10.5: A basic Markov Model describing the three possible states for a two-subsystem design

The arrows indicate potential failure and repair transitions between states with the failure and repair rates for each. Different failure rates among subsystems naturally introduce additional variables, but the computations remain the same.

Markov Models can account for multiple combinations of failure conditions and the effect each has on system performance. This offers a better view of the comparative severity of different subsystem failures and what kind of degraded performance can be expected.

Markov Models are very useful in calculating the cost/benefit analysis of steps designed to reduce failure rates at various places within a system—essentially putting a "time and trouble" cost on any possible subsystem failure, which is particularly valuable when considering how difficult it is to service tower-mounted wireless communications equipment. It can also inform design decisions at the planning stage, taking into account accessibility factors early in the process. The downside to the Markov Model, however, is that it cannot assign a single MTBF value or failure rate to the system as a whole.

Reliability factors

Now that we are able to determine system reliability by multiple methods, we can examine what can be done to improve that reliability. These measures start in the design phase and carry through to installation and maintenance practices.

Product complexity is a primary factor to consider. Simply put, adding more components means adding more opportunities for failure. Take the integrated remote radio head (RRH) (figure 10.6).

With thousands of electronic parts built into a single device mounted in an outdoor environment, the predicted failure rate may be as high as 5 percent per year. This rate takes into account the ambient temperature, internal temperature and the RRH's heat dissipation features, as defined by Telcordia SR-322 software. Reducing the number of components in this or any device will directly increase its reliability.

10.6: A compact, tower-mounted remote radio head

Redundant hardware improves reliability by increasing the number of states in which the system may operate, adding flexibility to address service levels and repair schedules. However, redundant hardware will not reduce maintenance costs and it requires a greater up-front investment.

Heat dissipation is vital to the long-term reliability of any electronic system or subsystem, whether mounted atop a tower or located in a ground enclosure. For instance, a 60-watt amplifier may generate an internal temperature rise of 25°C to 30°C, which, when added to an ambient temperature of 25°C, yields up to 55°C of heat, exceeding the default operating temperature of 40°C found in the Telcordia SR-322. Recall that reducing operating temperature by just 10°C may reduce failure rates by 50 percent.

Thermal limitations relate to how heat dissipation is handled in a device. In the example of the RRH, front- and rear-mounted heat sinks arrayed in fins dissipate internal temperature rise into the air. The larger the fins, the more heat can be transmitted away. Limitations appear in the form of mounting orientation, available space on the mount and the physical size of the RRH itself.

Environmental issues are a key factor when dealing with electronics mounted outdoors atop a cell tower. Temperature variations, moisture, lightning strikes and other local conditions all play a part in how reliability is measured and improved. Each consideration should be thoroughly qualification tested and take into account prevailing industry standards.

Thermal design considerations

- Robust margins for thermal tolerance
- Design to conform to outdoor cabinet specifications
- Integrated thermal protection against over-thermal conditions

Mechanical considerations

- Resistance to high winds and vibrations on rigid mounting
- Accommodation of expansion and contraction
- Mechanical change-induced drift compensation

Atmospheric considerations

- Resistance to water infiltration
- Resistance to corrosion, fading and peeling
- Connectors, seals and gasket design
- Proper lightning mitigation (shielding and grounding)

Installation practices are just as important as design factors when it comes to ensuring reliability. As discussed in chapter two, it’s vitally important to work with a competent and experienced cell site services company with well-documented safety records and tower climb-certified technicians to handle both mechanical and electrical services.

Qualified technicians will reduce the chances of improper lightning protection, poor connections, mishandled feeder cable and weatherproofing problems. In the long run, maintenance and troubleshooting are much easier and less disruptive to your network when trained professionals handle your work.

Reliability testing

A number of reliability test programs are designed to improve product reliability from early design prototype to deployment. Such tests include the following.

Design verification testing (DVT)

Products are tested to electrical and mechanical specifications contained in their product specifications. Testing includes, but is not limited to:

	Temperature and humidity exposure	
	Antennas/RF components	**Outdoor cabinets**
Cold exposure	Test per IEC 60068-2-1 at -40°C for 24 hr.	Test to -40°C per GR-487-CORE.
Heat exposure	IEC 60068-2-2 at +70°C for 24 hr.	Test to +46°C per GR-487-CORE.
Temperature cycling	IEC 600068-2-14 cycling between -40°C and 70°C for 96 hrs.; dwell times at limits shall be 1 hr. past chamber equilibrium and transition times between limits shall be less than 2 hrs.	Test from -40°C to +50°C per GR-487-CORE.
Damp heat (humidity)	Test per IEC 600068-2-30, Test Db; one 24-hr. cycle; 9 hr. at 25°C / 95% RH and 9 hr. at 40°C / 90% RH with 3-hr. ramp transitions.	Perform 7-day temperature/humidity cycling per GR-487-CORE for outdoor cabinets.

	Corrosion (salt mist)	
	Antennas/RF components	**Outdoor cabinets**
Continuous exposure	IEC 60068-2-11 Test Ka (ASTM B117) for a minimum of 720 hrs at 35°C with a salt mist concentration of 5 wt% NaCl	720 hrs. per ASTM B117 and GR-487-CORE
Cyclic exposure	IEC 60068-2-52 Test Kb (Severity Level 4 – 2 cycles) at 35°C with a salt mist concentration of 5 wt% NaCl	

	Ingress protection	
	Antennas/RF components	**Outdoor cabinets**
